children. Pintner (31) had reported in 1928, "The mental alertness of the deaf as measured on the Pintner Non-language Tests was on the average about three years behind hearing children of the same age." In contrast with this, Bishop (32) reported in 1936, "For the ninety children studied, the intelligence quotients on the Arthur Performance Scale ranged from 152 to 68. The interquartile range was from 84 to 106. The median was 97, the mode 97 and the mean 97.16 for the group." The children examined constituted "as nearly an unselected group (from the standpoint of intelligence) as one can find in the general school population."

A modification of Form I is the first scale used in measuring the ability of American Indian groups to yield an average rating comparable to that of the group against which the scale was standardized. In a survey carried out by the United States Indian Service (33) with the cooperation of the University of Chicago in 1942, 670 Indian children were tested in eleven communities of six different tribes. The mean I.Q. was 100.11 as compared with a theoretical mean of 100. Judging from these results, the modified Form I appeared to be "culture-free." Cattell, (34) Feingold and Sarason in 1941, in their search for a culture-free intelligence test state that of the tests investigated "the A.C.E. seems most susceptible to cultural influence and the Arthur least." The authors report of their own Culture-Free Intelligence Test II, that it "is shown to be as valid as the Terman-Merrill and as culture-free as the Arthur: it is the only scale that combines both of these advantages."

Loudon and Arthur report that patients with a reading disability described by Hinschelwood (35) as "Congenital Word Blindness" tend to earn a rating on Form I of the Point Scale of Performance Tests that agrees more closely with the Binet rating obtained after satisfactory reading skills have been developed than does the Binet rating obtained before they have learned to read. (36)

Comparison of 974 I.Q.'s obtained on Form I, with I.Q.s obtained by the same subjects on the Binet shows a P.E. (37) (Otis formula) of less than five points at all levels except 12 years, 15, 16 and adult. At the upper levels the performance ratings tend to run higher than those obtained with the 1916 Stanford-Binet. This is obvious from the upper Q values as well

as from a comparison of the medians, and can be attributed to the low ceiling of the Stanford-Binet. For 25 subjects tested on the Terman L and on Form I, the median Binet I.Q. was 143. The median chronological age was 19 years 7 months. The highest I.Q. earned on the Terman L was 162; the highest earned on Form I was 185. The correlation between the two sets of I.Q.s is about that generally reported between verbal and non-verbal scales: $r = .73 \pm .09$. (38)

The assertion has been made not infrequently that dull subjects tend to rate higher on performance scales than on the Binet. For 432 dull subjects who had earned Binet I.Q.s below 95, the median algebraic difference between the Binet I.Q. and the I.Q. on Form I of the Point Scale of Performance Tests was ± 0 . (39) There appeared to be no general tendency on the part of those dull subjects to rate higher on that performance scale than on the Binet. For 111 bright subjects, all of whom had earned an I.Q. of 115 or above on the Binet scale, the median algebraic difference between the Binet I.Q. and the I.Q. earned on Form I was $+ 1.0$. There appeared to be no general tendency for bright subjects to rate lower on the performance scale than on the Binet in that investigation. (40)

Atkins, 1931, published a report on An Object Fitting Test for Young Children. (41) It was carefully standardized for use without verbal instructions. The norms are based upon 150 tests at each year level from 2.5 to 5.5, inclusive.

The Alexander Performance Scale, (42) 1932, includes three tests, one of which, Alexander's Passalong Test is a manipulative puzzle standardized as a test for the upper age levels.

The Minnesota Pre-School Scale, (43) 1932, by Goodenough, Foster and VanWagenen was divided into (a) language scores and (b) non-language scores. The language scores were given double weight, originally, in the belief that language tests possess a higher predictive value for future brightness than do non-verbal achievements. A report on the predictive value of the Minnesota Pre-School Scale (44) by Goodenough and Maurer, 1942, states that in practically all comparisons the non-verbal scale of both forms, though shorter and therefore less reliable, was found to be a little more closely related to all later tests than was the verbal scale. This report resulting from a careful and

detailed study of predictive value was recognized as a distinct contribution to the field of non-verbal testing, even though the scale under consideration cannot be used for deaf or non-English speaking children without modification.

The Cornell-Coxe Performance Ability Scale, (45) 1934, is "capable of presentation by non-verbal methods." It includes seven tests, most of which were included in the Army Performance Scale. The authors reported a correlation of .79 between Stanford-Binet mental ages and ratings obtained with their scale for 306 pupils from kindergarten through the eighth grade.

In 1936 the Ontario School Ability Examination (46) was prepared for use with the deaf or non-English speaking child, and those "who for any reason are lacking in language facility." It was tried out with deaf and with hearing subjects, then given to 288 deaf students ranging in age from 5 to 22 years. The author states that the results form "a fairly normal probability curve about the median 94." "Compared with tables for hearing children, the I.Q. table for deaf children suffers a more or less uniform shifting of six points to the left."

The Leiter International Performance Scale, (47) 1936, approached the problem of intelligence measurement from the same angle as the Binet. Beginning at the 2 year level, four tests are presented at each year level up to and including 18 years. The entire scale has been standardized without the use of any language. Norms have been established for 710 Chinese, 720 Japanese and for African native groups as well as for "Caucasian" children. Mental age is calculated as it is in all scales of the Binet type. "The correlation of this performance test with Binet is .79."

The Wechsler-Bellevue Scale, (48) 1939, resembles the Minnesota Pre-School Scale in that it is made up of two independent scales, a verbal and a non-verbal. A significant contribution to the measurement of adult intelligence is the table (49) equating average reaction levels at chronological ages of 20 years and above with average reaction levels at chronological ages below adulthood. According to this table, the average reaction level of the individual 20 to 24 years of age is equal to that of the average individual 15.5 years of age, while that of the average individual 55 to 59 years of age approximates that of the average 12 year old.

These values, when verified for a wide sampling of groups by other investigators should be as valid for any other scale used for measuring adult intelligence as for the Wechsler-Bellevue for which it was constructed. The author states, "The median difference between Performance and Verbal I.Q.s for our scale is approximately 8.7 points"; and $r = .71 \pm .018$. (50)

In a Comparison of the Wechsler-Bellevue, Revised Stanford-Binet and American Council of Education Tests at the College Level, (51) results were reported for 112 college freshmen. "The Wechsler-Bellevue verbal scale correlated more highly with the other measures than did the Wechsler-Bellevue full scale, while the correlation of the Wechsler-Bellevue performance scale with the other tests was so low (.19 — .39) that doubtful validity at the college level is indicated."

The Carl (52) Hollow Square Scale, 1939, was developed from the Hollow Square Test (53) by Dearborn, Shaw and Lincoln. It is designed for adults and for children over 10 years of age. The directions are said to be difficult for younger children to comprehend. In spite of this, the author states that the test lends itself easily to use with the deaf and dumb through pantomime directions. For 521 adults the correlation ("adjusted Pearson r ") between Stanford-Binet I.Q.s and I.Q.s obtained on this test was $.785 \pm .011$, while the P.E. of estimate was 7.49.

In 1944, A Non-Verbal Test of Logical Thinking (54) reported a stencil design test that utilizes a third dimension in constructive thinking. It was devised to replace the Kohs Block Design Test in the Revised Form II of the Point Scale of Performance Tests (55) in order to avoid the high degree of practice effect shown by the Kohs test in retest scores at the higher age levels. This Stencil Design Test gives evidence of measuring general ability at age levels 4.5 to 15.5 inclusive, and also of indicating special ability in fields demanding logical thinking. Because of the spatial relations involved in the problems presented, it gives promise of usefulness in psychiatric clinics.

The Revised Form II of the Point Scale of Performance Tests shows a correlation of .78 with Binet I.Q.s for 171 subjects.

During the period of development of non-verbal scales made up of tests of the manipulative type, a variety of non-verbal tests of the

paper and pencil type were being published. Among the earliest of these was the Pintner Non-language Test. (56) Among the most carefully presented from the statistical standpoint is the Culture-Free Intelligence Test (57) by Cattell and his co-workers. The advantages of the paper and pencil non-verbal tests presented by pantomime are the convenience of the material, the possibility of use as group tests, and ease of scoring. The disadvantages are the frequent use of unclear drawings and of drawings too small to see with ease, the monotony of the task when successive tests all depend upon visual discrimination of small differences, and the lack of opportunity to observe the subject in a variety of situations.

With the development of the Binet scales, the standardization of performance scales and the publication of standardized tests of school achievement, the study of test "profiles," and of patterns of success and failure on tests of different kinds of ability was initiated. In these, ratings on separate scales were studied as parts of a composite whole and not as isolated facts. The reports of Bijou, (58) of Arthur, (59) of Wechsler (60) and other investigators have indicated the usefulness of performance scales in studies of the intellectual organization of subjects presenting problems of adjustment.

In a study of Primary Mental Abilities (61) in 1938 by Thurstone, 56 psychological tests, some verbal and some non-verbal, were given to a group of 240 volunteers. The scores were treated by multiple factor methods. The preface to the report states "When this study was planned, we postulated a number of tentative psychological categories or factors—the primary factors that have appeared have a general relation to the tentative categories with which we started, but they are not identical with the tentative categories. We had postulated a verbal factor, but we found two distinct verbal factors in the analysis. We found that the number factor is highly restricted. We had postulated different reasoning factors for verbal, numerical and spatial relations, but this tentative classification was not sustained. The reasoning tests revealed two factors that we have called "induction" and "deduction," the latter being less clearly indicated than the inductive factor. These reasoning factors seem to transcend the immediate characteristics of the material of the tests." It is studies such as this that assure the psychologist experi-

menting with performance scales that a wide variety of abilities can be measured without having recourse to verbal material.

Most tests are "trade tests" in that they are devised to measure ability from the point of view of some practical purpose. Modern statistical method is being applied in the search for valid criteria for the specific purposes to be fulfilled. The more specific the purpose and the more nearly valid the criterion, the easier becomes the task of gauging the usefulness of the test.

When tests are available for measuring accurately many abilities from many different angles, psychologists may be able to formulate more clearly the problem of measuring general intelligence both with verbal scales and with performance tests. In spite of recent progress, the measuring of intelligence, as a science and as a profession, appears to be still in its early infancy.

PERSONAL DOCUMENT ANALYSIS.

—Civilized human beings are, without exception, document makers, and recording experiences in symbolic forms constitutes a large segment of human behavior. Nevertheless, psychological document analysis to date performs only a minor role in the field of psychology. Clearly, the contradiction between the availability of subject matter and the minor use of it must be overcome sooner or later. As Dr. John K. Benton once observed, "The academic psychologist characteristically scales down his subject matter to the level of his own limited methodology." Psychology, however, is an expanding, self-critical discipline, and some progress in document analysis has been achieved very recently, while there is good reason to predict much greater progress for the near future.

Early in modern psychology's development the personal document was used for three main purposes. First, it was used to illustrate and to probe the psychology of adolescence (Stanley Hall). Second, personal documents were used as data in the psychological study of religious experience and behavior (E. D. Starbuck and William James). Third, document analysis was used in a quasi-clinical context, to illustrate some psychoanalytic theses concerning individual development (S. Freud). These early workers neglected giving any attention to the methodology of personal document analysis, and the methods which they actually employed were incidental.

Also incidental were the methods more recently applied by certain social scientists who

have used personal documents on the one hand to illustrate the introjection of culture, and on the other hand, as data which reveal what personal motives have activated certain social movements. In a recent monograph titled "The Use of Personal Documents in Psychological Science" (1941), Professor Gordon W. Allport contends that document analysis is among the critical areas in which psychology and sociology must develop mediating categories. The monograph mentions such sociologists as Znaniecki and Blumer as having made some preliminary contributions in this direction. Their work, however, must be classified as primarily sociological.

Meanwhile, the depth psychologists have given continuous attention to personal documents. Such psychoanalytic journals as *Imago* have carried essays by many different writers who are interested in the creative secrets of literary, artistic and philosophical geniuses, and who discuss the personal documents produced by such geniuses as possible sources of insight. Yet few serious methodological studies have been forthcoming from the psychoanalytic school. A noteworthy exception was Dr. Harold G. McCurdy's article titled "Literature and Personality," which appeared in *Character and Personality*, 1939, VII. In the first installment McCurdy discussed how the analysis of literary productions and the analysis of the life histories of the men of letters may be reciprocally useful, and in the second installment a systematic analysis of the novels of D. H. Lawrence was presented. This analysis employed such familiar Freudian concepts as "projection," "identification," "symbolization," "condensation," and the "Oedipus complex." Carl J. Jung and some of his followers, such as the English clinician Helton Godwin Baynes, have encouraged their patients to express their personal problems in drawings and paintings, employing media which guarantee some permanence to the work. This type of research converges with the so-called projective techniques, and would not ordinarily be identified with personal document analysis, but it is important to note that the boundary line between the two types of research is somewhat arbitrary.

Dr. Alfred L. Baldwin has investigated the possible use of document analysis in the psychology of personality, properly so-called, and pursued apart from extrinsic interests such as the clinical or the sociological. In an article

titled "Personal Structure Analysis" (*Journal of Abnormal and Social Psychology*, Vol. 37, No. 2, April, 1942), he suggests that the major personal attitudes provide the content most frequently expressed in any intimate and prolonged personal document, and that the frequency of the relation of contiguity between any two types of expressed content is a measure of the association between any two personal attitudes. Baldwin's subject matter for this study was a collection of personal letters written by a middle-aged woman during a period of some eleven years. His analysis, which used the above mentioned principles, was rigorously quantitative and was exhaustive. Such a method would seem to be adequate so far as it goes for the analysis of those documents in which neither deliberate nor involuntary (and, perhaps, "unconscious") disguise of contents or connections plays a part. For those cases in which disguise is operative, symbolic analysis, stylistic analysis and other methods would be necessary as supplements to Baldwin's statistical treatment of the "surface" materials. Of course, environmental contingencies might in some cases cause a document writer frequently to mention matters which concern him only superficially, and so it would seem that frequency, as a criterion of personal importance, should be employed with caution, and some attempt should be made to rule out matters of mere contingency.

Charlotte Buhler, the well-known European psychologist of personality, has derived major conclusions concerning personality from the systematic study of large collections of personal documents. There is little doubt that in the future, collections rather than single documents will receive greater attention than was usual heretofore. Buhler's work was exceptional also in that it stressed the time-dimension of personality. Every life history, as partly revealed through the personal document, was found to involve a few major personal goals and tasks which became increasingly definite with maturation and learning, and which became increasingly unified. Feelings of expanding vitality and personal influence characterized development through young adulthood, but afterwards a greater tendency to surrender to frustrating circumstances became evident. Expansion was found to give way to restriction, and boasting to resignation. Thus Buhler depicts the time-Gestalt of human life along lines which, per-

haps, may be called pessimistic. The personalities which she studied through the personal documents seemed to achieve no full reconciliation between their evaluational attitudes and their mature sense of finitude and personal limitation. It may be asked whether such failure characterizes human life histories generally, or whether some fairly constant factors in central European secular culture and ideology in the middle decades of the twentieth century were responsible for Buhler's findings. Certainly the personal documents studied by William James and cited in his book, *The Varieties of Religious Experience*, would provide basis for quite different conclusions.

A personal document may be investigated primarily as a clue to the productive personality, or it may be investigated primarily as a system of expressions which reveal, or partly reveal, a personal world. Personal worlds, like personalities, have their histories, and indeed, a personal life quest always proceeds within the frame of reference provided by a particular and also changing personal world. Would comparing and contrasting different personal worlds, as expressed through personal documents, be logically equivalent to comparing and contrasting the different productive, developing personalities? A phenomenological analysis of personal documents would contribute to the answer to this question, if an integral phenomenology must be a systematic exploration and description of experience as uniquely personal. True, the phenomenological appreciation of a personal world which is mediated by a system of expressions would be the type of direct awareness which follows partly inferential investigation, rather than being that direct intuition of data which precedes deliberate inference. In no other way could an integral phenomenology be more than mere introspection, but the study of behavior as expression, in contradistinction to its study within a physicalistic universe of discourse, serves truly phenomenological purposes. And personal documents are systematic expressions of personality.

Which documents constitute adequate expressions? That question was considered in R. F. Creggan's article titled "The Phenomenological Analysis of Personal Documents" (*Journal of Abnormal and Social Psychology*, Vol. 39, No. 2, 1944). It was urged that various criteria both intrinsic to the document and extrinsic to it

should be applied in order to estimate how fully the expressions in it reveal the personal world in the first place, and more indirectly reveal the productive personality. The same article suggested that both intuition and inference are legitimate methods in document analysis on the condition that detailed conclusions, however reached, are validated by the phenomenological coherence principle. The personal document was said to provide the following kinds of evidence about the personal world: direct statements, significant contiguities, symbolic interpenetrations, and stylistic correspondences. A complete analysis was said to reveal both formal and material attributes of a personal world, and to reveal both local and more general attributes of both types. Furthermore, that the development of a personal world, as expressed in a temporally inclusive document, involves both material and organizational changes, while the total development sums up many local trends was stressed.

Some examples of fairly general content in a personal world would be the type of values which a person stresses and the type of causality in which he believes. Such factors would be general enough to find expression in many different areas of concrete personal concern. The degrees and types of differentiation and integration of content would be identified as formal characteristics, while such factors as personal directionality and personal distance would be neither exclusively material nor exclusively formal, but organically formal-material. The above mentioned article applied these and related principles in the analysis of a student diary covering four years of college life. The analysis showed that the locus of the personal world progressively changed on several dimensions, each of which indicated variable characteristics which are shared by many personal worlds. As the person faced novel situations and overcame various conflicts, the structure of the personal world evolved.

Personal document analysis is approaching methodological maturity at the present time, and some of the investigations mentioned above mark definite stages in its progress. Continued methodological advancement and a widening range of application for document analysis may be expected primarily because the personal document provides the most conclusive data concerning what may be called the higher stages

of individual development. In the major personal diary, the diversified collection of individual correspondence, the secret autobiographical attempt, and in similar classes of extensive and intimate documents, the person frequently states his conflicting viewpoints concerning values and concerning the relations between his values and reality as experienced and inferred within the frame of reference of the unique life history. And it is these most complex personal preoccupations, these highest levels of personal development, which psychology must explore and understand if it is to make any decisive contribution to the human quest in an era of hitherto unimagined cultural and spiritual conflict and searching.

PERSONALITY (Latin, *persona*, *personalitas*; French, *personnalité*; German, *Persönlichkeit*; English, *personality*, *person*, *self*).

I. THE CONCEPT IN PHILOSOPHY AND PSYCHOLOGY

The history of the word *personality* reflects the problems encountered by any thoughtful attempt to define its meaning. First used among the ancients for the dramatic mask, it soon became the name for the individual role. It was when the Church Fathers wanted to suggest the nature of the God who expressed himself in three roles that the metaphysical meaning of the term came into being. Thus, when Leibniz distinguished man from animal by calling him

a *person*, or a rational, self-conscious, continuous, incommunicable and unique substance, he epitomized the main philosophical answer to the metaphysical problem of the source of identity and continuity in individual change. We are indebted to Kant for extending the term to its most significant ethical sense, as designating a rational, free agent who should never be treated as a means only.

If these problems of the unity and continuity of individual structure and the ideal of human conduct seem remote from scientific psychology, the connection becomes evident once we recall prolific discussions of the integration of personality, the nature of mental health, and the underlying units of behavior. When psychology decided to free itself from the *mater scientiarum*, it did not soon develop a new vocabulary. For the philosopher, the words *spirit*, *soul*, *self*, *consciousness* have, in the main, referred to the unified, private, non-spatial subject or agent in experience, though much less agreement can be found as to the nature and interrelation of each term. The words *person* and *personality* have invariably referred to that quality of selfhood which was capable of self-conscious rationality and ideals. The student is not hard put to discover in such thinkers as Anaxagoras, Protagoras, Plato, Aristotle, Plotinus, Augustine, Aquinas, Descartes, Hobbes, Locke, Berkeley, Hume, Kant, Fichte, Hegel, Lotze, Renouvier, Jouffroy, Mach, Bradley, Royce, James, Calkins, Brightman, Whitehead, Spearman, Aveling, Stern, and G. W. Allport the fundamental historical concern to explain the unity and multiplicity, continuity and change, identity and difference within human experience. Psychological discussions have sometimes wittingly and sometimes unwittingly moved away from these problems.¹ Psychologists have either assumed the existence of an epistemological or metaphysical subject, or else have repudiated the whole problem as meaningless, and have moved on to the level of description, in the hope, perhaps, that a better solution might be forthcoming.

However, a more reasonable transition from the metaphysical and epistemological to the psychological description of the self was made possible by Kant's distinction between the *subject I*, or pure ego, which thinks and feels, and the *I* which the pure ego knows and feels as its object, the empirical self or *me*. When psycholo-

gists and philosophers challenged the purity, substantiality, and singularity of the self, only the empirical self was left. When the psychologist-philosopher William James suggested that a man's *empirical* self could be considered "the sum total of all that he can call his, not only his body and his psychic powers, but his clothes and his house . . ."² he was opening the way to the psychological description of personality.

But scientific analyses of personality struggle with the same problems: What is personality? Does it have unity, and, if so, how is this to be construed? What is innate and what is developed, and how? How is the conscious personality related to the unconscious? How are the personalities of others known? Many empirical data have been and are being garnered. The *interpretation* of these data, however, turns invariably upon the psychologist's answer to these fundamental questions. As with philosophers, so with psychologists, all interpretations have been affected by the methodological presuppositions of each investigator. In view of the parallelisms and similarities which exist between the problems, data, description, and interpretation at the philosophical and psychological levels of analysis, one can only deprecate the unwillingness of natural partners to study and understand the contributions of the other.

II. EMPIRICAL BEGINNINGS

When Bacon said, "The first article, therefore, of the culture of the mind, will regard the different natures or dispositions of men. . . . And I cannot sometimes but wonder that this particular should be generally neglected . . ."³ he was justly chiding scholars and not "the common discourse of men" for neglecting the concrete individuality of persons. Brief note must be taken, nevertheless, of early beginnings.

When Theophrastus, in the fourth century B.C., penned his remarkable "characters," each dominated by a comprehensive personal trait, little did he realize that one day an Adlerian would demand to know a person's *style* of life. Nor did Hippocrates dream that endocrinologists would substitute hormones for humors and insist that the chemistry of the body had indelible effects on emotional disposition.

The physiognomic diagnoses in which both scientists and quacks engaged since Aristotle's observations have led to careful correlation of personality traits and bony structure, muscular

set, and physique. In the phrenological area, Franz J. Gall (1810) was convinced that quantitative variation would account for the individuality of different persons.

Still another characterological strand emerged when A. Bain (1862), A. Shand (1896, 1915), and W. McDougall (1908) rejected intellectualistic psychology and interpreted individuality as the channelization of innate emotional energies. In France, C. Fourier (1822) emphasized not only the *dominant* motives of personality, but also the *manner* of their execution as affected by *tonic* passions. M. de Biran (1887) also reacted against mechanistic associationism and insisted that the self, far more than Hume's series of experiences, is an experiencing, unified agent which becomes conscious of itself as its *will* meets resistance—a voluntarism which was to be developed in Cousin's (1859) doctrine of spontaneity of will, and later in Brentano's (1874) activist concept of mind.

However, it was not until Sir Francis Galton (1884) convincingly challenged J. S. Mill's skepticism as to the applicability of experimental method in the study of personality (not only by the use of statistical and correlational techniques but by the use of experimental controls especially in the study of expressive movements) that the present experimental impetus got under way. -

III. THE PROBLEM OF DEFINITION

We have noticed that psychological science is concerned with empirical individuality (Persönlichkeit), and not the inner unity-giving person (Personalität). But nothing like agreement as to the definition of personality is to be found either within academic halls or psychoanalytic clinics. D. W. MacKinnon has observed:

✓"American psychologists have tended to emphasize the parts or units which, summed or integrated, could be thought to constitute personality, especially those elements which they had reason to believe were common to all individuals. . . . German psychologists, on the other hand, have been more inclined to think of personality as a unique whole which cannot fruitfully or legitimately be analyzed into smaller component parts."⁴

Convinced that uniqueness cannot be described or explained, German psychologists have

turned either to typologies or to the understanding of a personality in its cultural and historical setting. The work of G. W. Allport in America, in its insistence that psychology develop a methodology which can take account of individuality, is at once a critique of purely nomothetic analyses, of typologies, and of intuitionistic accounts. But here again differences in the conception of psychological science reflect in turn differences in conviction on the mind-body, teleology-mechanism, heredity-environment, and man-society problems. These conflicting tendencies pervade the following survey of definitions.

Atomistic trends are exemplified in Prince's definition of personality as "the sum-total of all the biological innate dispositions, impulses, tendencies, appetites, and instincts of the individual, and the acquired dispositions and tendencies—acquired by experience."⁵ This enumerative or *omnibus* conception is transformed once attention is focussed on the functional order in mental life. Thus H. C. Warren and L. Carmichael emphasize the *integrative* aspect:⁶ "Personality is the entire mental organization of a human being at any stage of his development. It embraces every phase of human character: intellect, temperament, skill, morality, and every attitude that has been built up in the course of one's life." When, in turn, the inner order of personality is conceived of as hierarchical, as in James' classical distinction (1890) of the material, social, spiritual, and knowing selves, *hierarchical* definitions result. However, writers like McDougall, Bridges, Martin, Blondel and Murray emphasize a hierarchical organization of purpose. The *biological* and *behavioral* emphasis is found in definitions like those of J. B. Watson, C. N. Rexroad, E. J. Kempf, A. O. Bowden and L. Shaffer (see section X), which stress adjustment along with integrative or omnibus structure. The *social* type of definition stresses the cultural setting of personal development. Thus L. Marcuse: "Personality is the convergence of all essential, cultural tendencies in one mind. The more culture one has, the harder it is to be a single personality."⁷ But thinkers like M. Schoen realize that: "If all the members of any one social group acted alike, thought alike, and felt alike, personality would not exist."⁸ Accordingly, they emphasize the social distinctiveness of the individual, and with R. H. Wheeler see personality as "that particular pattern or balance of organized reactions

which sets one individual off from the other."⁹ Since all of these definitions conceive of personality as a product of learning, it is easy to see why R. S. Woodworth was led to deny personality any substantive intent and give it a purely adverbial meaning, thus: "Personality refers not to any particular sort of activity such as talking, remembering, thinking, or loving, but an individual can reveal his personality in the way he does any of these things."¹⁰

*A *personalistic* definition which synthesizes the hierarchical, integrative, adjustive, and social contributions, while stressing uniqueness, is that of G. W. Allport: "Personality is the dynamic organization within the individual of those psychophysical systems that determine his unique adjustments to his environment."¹¹

It may have occurred to the critical observer that a serious ambiguity lurks in all of these definitions; namely, in the word *individual*. It is the individual's personality; it is the individual's learning, or mode of adjustment. Clearly the individual is not at once the personality learning and the personality learned, the original adjuster and the adjustment made, the organizer and the organization produced, the unifier and the acquired unity. The philosophers, we recall, faced this problem of subject-object, of identity persisting through change, in their doctrines of the soul and self. The informed psychologist, offended by unempirical formulations of substantive selves, deserted the problem and seems to have stretched the question-begging term "individual" over the lacuna. The uninformed psychologist has read somewhere that theologians and philosophers (who, of course, deal only in unempirical speculations!) concern themselves with the soul and the self, so he concludes that this problem cannot possibly concern him as a scientist. But it would seem that the psychologist who would speak clearly not only to his comrades but to readers who care to know more about themselves as persons than about the future of technical psychology should at least offer some exposition at this point. Would that the problem were only one of language! As long as acute psychologists realize that "the crucial problem of psychology has always been mental organization (association)," ¹² some sort of agent-subject needs to be included within the psychologist's "frame of reference." James Ward and McDougall among the British, Lotze and re-

cently Stern among the Germans, Brentano among the Austrians, Renouvier among the French, and Mary W. Calkins were convinced that psychology could not be intelligible at this point without postulating a non-spatial self as the "basal unit of psychology." Miss Calkins, while not accepting an "embodied self," was willing to concede that "this biological form of personalistic psychology provides a middle ground in which most schools of contemporary psychology may meet."¹³

The present writer has suggested that the "individual" be replaced by a *psychological self*, a "multiform dynamic unity," to use Stern's term. The native activities of this self, which text after text in *General Psychology* expound, are: (at least) sensing, remembering, imagining, perceiving, thinking, feeling, and wanting. This knowing-wanting self may be further conceived, within the psychological household, along lines of psychophysical neutrality or as psychological parallelism, or as double-aspect theory, or interactionism. But it would supply the persistent, unifying, active agent which, in its contacts with the world, adjusts its powers and develops its unique personality. On this view, the synthetic definition of Allport could be transformed to include the essential contentions of the self-psychologists thus: A self's personality is that self's dynamic organization of its own unique psychophysical wants and abilities which renders adjustments to its environment unique.¹⁴

IV. THE PROBLEM OF CHARACTER

Character, the citadel of human personality, has run afoul of the stubborn determination of recent psychologists to rid themselves of unempirical and philosophical concepts. How could this ambitious young science hope to enter the academy of the sciences with an "uncaused" will as the ground of character? A long line of moralists extending from Plato through Kant to the present have insisted that character is the product of a will free to determine action in accordance with reason. Kant went so far as to propose that the acid test of ethical action was rational willing, free even from conative inclination. This extreme intellectualism did not survive the more balanced emphasis on biological and emotional determinants of human behavior. The British especially thought of character as a part of personality; namely, the integration of drives which sustained effort in

tional stimulation, his customary strength and speed of response, the quality of his prevailing mood, and all peculiarities of fluctuation and intensity in mood; these phenomena being regarded as dependent upon constitutional make-up, and therefore largely hereditary in origin."²³

VI. DESCRIPTION OF PERSONALITY AT THE TYPOLOGICAL LEVEL

A. *The Approach from Abnormal Psychology.* E. Kraepelin, striving to reduce the baffling variations of abnormal phenomena to some sort of order, drove (1899) the entering wedge which split psychoses into *manic-depressive* and *dementia praecox* (the latter to be supplanted [1924] by Bleuler's more comprehensive category, *schizophrenia*). Neurotic phenomena were dichotomized by P. Janet (1894 and 1903) into *hysteria* and *psychasthenia*.

What concerns us especially is that the humanistic and scientific urge to understand and prevent the incidence of these diseases led to the study of the predisposing conditions in the normal personality. This seemingly fertile problem of correlating abnormal types with normal types has produced division after division of normal personality structure and a corresponding analysis of dominant traits for each type. The interested reader will appreciate MacKinnon's informing tabular presentation and discussion of these dichotomous typologies.²⁴

The influential typology of C. G. Jung is well known. The words *introvert* and *extravert* have become part of everyday language even though their supposed relation to schizophrenia and hysteria may be far-fetched. Critics do not always realize that for Jung no person is simply introverted or extraverted, but he is introverted or extraverted in intellect, or sensation, or feeling, or intuition.

B. *The Approach from Cognitive Function.* O. Külpe, R. Scholl, E. R. and W. Jaensch built their classification around notable individual differences in perception and imagery. Scholl, building on the discoveries of Külpe that subjects in reporting on colored forms tended to notice *either* form *or* color, attempted to correlate color or form dominance with other personality traits. H. Rorschach differentiated his extratensive from intratensive types by the predominance of color over motor response respectively. The Jaensch brothers have meanwhile

built what became an unwieldy typology around dominance of spontaneous and variable eidetic imagery (B type) and the involuntary, obsessive eidetic imagery (T type). But soon came the realization that the B and T types were themselves the extremes of two more comprehensive types, the *integrate* and the *disintegrate*. In the integrate type all mental processes interpenetrate, and the imagery of this type at the extreme is eidetic. In the disintegrate type eidetic mental processes are more differentiated, but in the extreme this type lacks eidetic imagery. The integrate individual stresses feeling, is spontaneous, out-going, artistic, and plastically practical; the disintegrate emphasizes will, is the inwardly oriented, rigid, unimaginative theorist.²⁵

C. *The Constitutional Approach to Typology.* Interwoven with the problem of temperament and its relation to personality is the problem of physical type. The Hippocratic dichotomy of physical types gave way to a trichotomy in the nineteenth century when L. Rostan differentiated digestive, muscular, and respiratory-cerebral types. It is, however, to two nineteenth-century Italian anthropologists, A. di Giovanni and G. Viola, that credit must go for attempting quantitative measurements in defining constitutional differences and developing anthropometric techniques. Reports by Viola and his followers, especially Naccarati (1921), of an appreciable correlation between short body type (microsplachny) and high intelligence have not been supported by other students. It was left to the German scholars, F. W. Beneke and E. Kretschmer, to reinforce Rostan's typology empirically, and to suggest correlations with bodily and mental diseases.

The typology of Kretschmer highlights the cycloid (related to manic-depressive insanity and pyknic constitution) and the schizoid (related to schizophrenic insanity and leptosomic and athletic constitution) types. The *cycloid* is basically good-natured and sociable, a person who swings from cheerfulness to depression. The *schizoid* is basically humorless and unsocial, a person who has warring within him at the same time shyness, oversensitive refined feeling, and insensitive, dull-witted, and sulky affectivity. It should be emphasized that these cycloid and schizoid traits are, on the one hand, transitional developments short of their clearly abnormal counterparts, and, on the other hand, *not* necessarily related to the healthy biotypes

Kretschmer designated as *cyclothymes* and *schizothymes*.²⁶

The typological description of personality has, of course, drawn the javelins of many critics. Other constitutional investigators, including those in England and America, have discovered that the complex unity of personality structure does not reward attempts to correlate segments of the physical and fragments of the mental life. The exposure of weak correlations has supported the suspicion that all typological classification is essentially arbitrary. The sacrifice of personality uniqueness and gradation to convenience was too high a price to pay, especially when the personality was forced into the investigator's special interest, be it abnormality, temperament, or constitution. "In reality, types are valid only for a limited characteristic; they embrace a segment of individuality, but never the total individual."²⁷ Furthermore, the demand for common factors among complex individuals beguiled the typologists into considering the more observable traits intrinsic to human nature and explaining less tangible trait-clusters in terms of them, *without* further investigation. They approached personality from the more accessible first story, convinced that within they could find an escalator to take them into the higher human reaches.

D. *The Approach from "Understanding" or Values.* It is from this latter angle that the *Verstehendepsychologie* of W. Dilthey, E. Spranger, and K. Jaspers is particularly interesting. These leaders in *Geisteswissenschaftliche Psychologie* begin with life as experienced, and describe *that*; they resist atomistic "explanation" as they keep their gaze fixed on part-aspects of wholes.

Agreeing with Dilthey's conviction that "the *Strukturzusammenhang* is experienced,"²⁸ Spranger goes on to describe the types of meaning discoverable in and dominating the total organization of different personalities as they interact with their cultural environments. His actual procedure is to abstract a value-tendency in one life, idealize it, and then study the particular modifications it has undergone owing to historical, geographical, and personal circumstances. Spranger believes that unless there were such "ideal directive constants" to control productive imagination and cognition, no science of personality would be possible. He accordingly delineates his six ideal types, any of which may dominate the psychic activities of a given

individual in a culture. The *theoretical* man persistently seeks systematic order in experience; the *economic* relates all experiences to problems of bodily self-preservation; the *aesthetic* man emphasizes the form and harmony in his world; the *social* regards persons as ends in themselves; the political is inclined to translate all into *power*, while the *religious* man not only seeks but embraces unity in its cosmic meaning.

While this typology raises our psychological perspective and grapples with the psychology of *quality* as well as common factors in experience, it does not escape the arbitrary segmentation of typologies, even while it refuses to break the individual down into "components." There are other values besides these which might have been used, and other members of this school have suggested other typologies. But the fatal weakness of typologies is not overcome. The incompressible variety and individuality of persons is lost.

VII. CONSTITUTIONAL PSYCHOLOGY

The problems faced by constitutional psychology has stimulated a new constitutional approach whose essential assumption is "that human behavior is a function of bodily structure as well as of environmental forces."²⁹ Faced with the alternative: either give up the constitutional approach or give up typologies, these students gave up personality dichotomies and trichotomies. They substituted a systematic classification of bodily structures and then attempted a correlation of these with temperament. After careful analysis of many specially prepared photographs of human bodies, Sheldon was able to isolate primary constitutional components and work out a schema for grading human physiques. Physiques may be graded on a 1-7 scale for *endomorphism*, or relative predominance of digestive viscera over bone, muscle, and connective tissue, whose predominance would constitute *mesomorphism*. "*Ectomorphism* means fragility, linearity, flatness of the chest, and delicacy throughout the body."³⁰ Thus human beings are not typed but are seen to vary along dimensional axes for each of these primary components. A given physique may be characterized, say 335, about average in the first two components and more marked in the third—therefore *ectomorphic*.

Sheldon also believes that there is a correlation between these constitutional components

and temperament. After combing the literature and reducing the alleged traits of temperament to fifty, Sheldon, with the aid of factor analysis, discovered three "clearly defined" nuclear clusters of traits. The first, *viscerotonia*, correlated with endomorphy (*t* .79), "in its extreme manifestation is characterized by general relaxation, love of comfort, sociability, conviviality, glut-tony for food, for people, and for affection."³¹ *Somatotonia*, correlating (*t* .82) with mesomorphy, involves vigorous bodily assertiveness predominantly, while *cerebrotonia*, correlating (*t* .83) with ectomorphy, involves predominance of restraint and inhibition.

The identification of the three primary somatotypes, however, is merely the anchor for physical analysis.

"So many secondary variables still remain to be described that the horizon of individuality seems only to broaden and to recede to greater distance as the techniques of physical description mature to usefulness.

"Some of the important secondary variables are dysplasia (different mixtures of the primary components in differing regions of the body), gynandromorphy (physical bisexuality), texture (fineness or coarseness of tissue, aesthetic harmony of structure), secondary local dysplasias or hereditary local patternings of the primary components, often called racial characteristics, pigmentation, distribution of secondary sexual characteristics (gynandromorphic dysplasias and characteristic patterns), hirsutism and hair distribution, and so on."³²

In this psychology of constitutional differences, which replaces the rudimentary dichotomy of body and mind by the conception of a continuum, a new psychological faith is embraced. Starting "with the solid bone and flesh of the individual,"³³ it goes as far up as it can by systematically describing both physiological and psychological variables. The hope is that psychological analysis may become *total* analysis rather than simply *psychoanalysis*. The breath-taking audacity (or naïveté!) of this "total" program becomes clear in a statement like the following:

"We of the English-speaking world are repeatedly scolded because we faced a grave

responsibility in 1919, and flunked the test. Had we been able to define somatotonia, is it possible that we might have saved Germany [an 'historically somatotonic' people] from herself and ourselves from Germany?"³⁴

The main hope of the future of man becomes "discriminate breeding," once we understand how to isolate eugenically and eliminate the weak constitutional types!

VIII. PROBLEMS CONFRONTING SYSTEMATIC ACCOUNTS OF PERSONALITY

The psychology of temperaments and of types, whatever its weakness, did illuminate the persistent conviction that nature is no mere changing composite of elements passively reacting to external stimuli. Human nature, it was felt, has inner, enduring determinants which influence the course of life. Human beings, though differing from each other, have generic, innate similarities, such as physical constitution, temperament, intelligence. The basic problem confronting psychologists of personality accordingly became that of determining what the constants are, how constant they are, and how they change—a task which involves not only the study of human variables, but the effect of different environments on the individual. Underlying this whole question of change or learning is the problem of whether the introspected and observable stream of activity is goal-directed, totally or in part, or whether it is the concourse of essentially aimless, machine-like events.

Recent and contemporary approaches to personality are in fact different attempts to solve these problems (among others). In order to gain a fairly clear outline of the present situation, and at the unfortunate sacrifice of many interesting developments within each systematic outlook, we shall here be restricted to pivotal points of view.³⁵ Since much recent thinking has reacted against *hormic* theory, we may well begin our sketches with this "school."

IX. PURPOSIVE PSYCHOLOGY

A. *William McDougall*. The work of McDougall has been discussed so much from the point of view of instinct-theory that the essence of his thought has frequently been lost. His main concern is with "the organization of the affective life," which gives the lie, as he sees it,

to any analysis of human life as a mosaic of physiological or ideational "atoms" and to any intellectualistic view of motivation. McDougall needs no reminder that "personalities are infinitely various and complex," for he would insist that "each personality is in its degree an integrated unity of all its factors . . . a system of energies, each distinguishable part of which owes something of its nature to its place in the whole, and its active relations with all other parts."³⁶

1. Organization of Motives. McDougall's own reflections on personality were spurred on by G. F. Stout and A. F. Shand on the one hand, and by William James on the other. As he observed personality, he noted its stable, enduring organization around specific goals, a fact which contrasts sharply with the relatively vague orientation of emotion and feeling. Stout and Shand had observed that "interest progressively defines itself in cognition, and in defining itself transforms itself," and that "in the process of satisfying one interest new results are experienced which give rise to new interests."³⁷ It was McDougall who emphasized that such cognitive-affective dispositions, or sentiments, are not only functional units of character, but represent merely the first, child-like level of organization. Character formation in adults involves the hierarchical organization of sentiments around a dominating master-sentiment; namely, the highly complex and variable self-regarding sentiment.³⁸ McDougall is emphatic, as against Shand, that a sentiment is an *acquired* linkage of cognitive with affective dispositions.

This concept of sentiments and their organization around the self-regarding sentiment is not only fruitful in explaining many abnormal and social phenomena, but it enables McDougall to understand "those higher forms of activity which are properly called volitional, which express the integrated working of the whole personality, comprising both character and will."³⁹ For in a well-integrated character sentiments for concrete objects (e.g., money) would be regulated and dominated by sentiments for more abstract ideals (e.g., liberty). Volitional activity, therefore, depends on the way in which the sentiments are organized around the particular self-regarding sentiment. As McDougall remarks, Freudian pronouncements about the controlling function of the Ego and Super-Ego express the same contention, and it may be ob-

served that recent discussion about the organizational and directive function of ego-involvement suggest the same theoretical concept.⁴⁰

2. Tastes. In addition to sentiments the acquired personality structure includes tastes. While sentiments were introduced to describe the concentration of conative energy around specific objects, *tastes* are advanced to describe "many similar instances of acquired liking for particular modes of activity, both bodily and intellectual" (like chess or bridge).⁴¹ While tastes do not determine our goals, which spring from innate propensities and sentiments, they do "very largely determine our choice of means or modes of activity through which we shall pursue our aims and work toward our goals."⁴² While McDougall raises the "difficult question" as to whether tastes become independent sources of energy⁴³ and seems hesitant about making an exception to his underlying hormic principle, he finally suggests that tastes are not only acquired in the service of some sentiment or propensity but remain inactive and subside once conative support is withdrawn.

3. Propensities. This, in essence, once the innate factor of *temper* is added, is McDougall's view of personality organization as built from clues gleaned especially from Stout. But Stout left him unsatisfied when he asked the questions: If sentiments are highly organized dispositions, how are such dispositions formed? What are their components? He therefore felt driven, developing a suggestion provided by James' instinct-theory, to *postulate* his much-discussed list of instincts, which needs no repetition here. A central contention in his own view, despite the mis-reading of many critics, is that instincts (or propensities) do not involve rigidly prescribed trains of means-to-end movements, but are capable of varied adaptation in accordance with the special circumstances surrounding the attainment of the instinctive goal. McDougall's view that each instinct is accompanied by a primary emotion has been questioned even by adherents. Nevertheless, as C. Burt wrote in a recent Symposium,⁴⁴ subsidiary assumptions aside, it is not easy to gainsay McDougall's contention that there are complex inherited "cores" of impulse, or tendencies, which drive each member of a species, other things being equal, to perceive and pay attention to certain objects or situations. As we shall now see, this hormic thesis finds significant

acceptance and alteration in the thought of H. Murray.

B. *Henry A. Murray, Jr.* The problem-sensitive, architectonic system presented in *Explorations in Personality*, 1938, is an extremely careful attempt to embrace conflicting tendencies in "personology." While Murray's clinical methodology and outlook are strongly influenced by Freudian conceptions of personality, his theorizing is in fact a critical synthesis of McDougallian hornism and Lewinian configurationism.

1. Double-aspect Theory. At the outset Murray adopts that version of the double-aspect theory which states that "every conscious process is the subjective aspect of some regnant brain process, but not every brain process has a conscious correlate."⁴⁵ This theory not only justifies introspective description, but it also makes room for unconscious processes in personality. The personality for Murray is the dominant unity of brain processes, which interact, of course, with the bodily chemistry. This personal unity, while not what we have called the psychological self, is "time-binding," capable of conserving past, anticipating future, and therefore of continuity of purpose.⁴⁶

2. The Necessity for a Non-Mechanical Concept. Murray is impressed by the fact that an individual may achieve the same adaptation to environment despite the differences in the behavioral means used to produce that effect. As a matter of fact different means seem to be retained only as long as they aid in adaptation. In order to explain the relations of a given set of observable means-actions to each other and to the total effect (e.g., "the *resumption* of unpleasant work after interruption and the *increase* of striving in the face of opposition"),⁴⁷ Murray is forced to postulate an "invisible link," namely, a brain process, a persistent trend, need, or drive toward certain general goals. This hypothesis is further supported by the introspection of desires or tensions which, on the double-aspect theory, would be expected to have electrochemical counterparts. Thus Murray recognizes the fact which is central to "situational psychology," that there are stimulus-response sequences activated by tensions which they serve to reduce. But in opposition to behaviorism he interprets the data purposively, as "the lawful connection between a certain kind of stimulus and a certain kind of trend."⁴⁸

It must be immediately added, however, that

for Murray, while purpose is consciously felt as a "pull from the future," it is in fact a push from the rear, that is, "a strictly present" brain process that points and co-ordinates activity.⁴⁹ On the other hand, the need is not to be equated with visceral tensions or endocrine secretions; these are the sources of, but not, the need-processes. If this "working hypothesis" does not satisfy those "psychologists who bristle when 'purpose' is mentioned," they are reminded of Whitehead's rejoinder: "Scientists animated by the purpose of proving that they are purposeless constitute an interesting subject for study."⁵⁰ Still, though Murray is not a mechanist, it is clear that he is more of a "dynamist" than a purposivist of the McDougallian sort. His version of double-aspect theory, in which consciousness need not reflect the bodily process, helps, perhaps, to account for his unwillingness to allow consciousness of a non-existent future to affect present action. Here is another instance of difference on fundamental problems affecting psychological interpretation.

3. The Nature and Organization of Needs. Neither emotion, as with McDougall, nor reflexes, as with behaviorists, constitutes the essence of need. Emotion and action patterns are helpful indices of needs but a need always is an organic disturbance which directs means to the end of re-establishing equilibrium. Murray is insistent that every attempt to substitute the mechanical action of the neuro-motor system for dynamic needs introduces adaptive trends "surprisingly."⁵¹

A persistent difficulty for any need-psychology is that of distinguishing innate from learned needs. McDougall was forthright in defending the innateness of certain social and psychical propensities (like gregariousness and curiosity) as well as organic needs. Murray, however, seems more convinced of the innateness of his thirteen "viscerogenic" needs than of the twenty-eight "psychogenic." The psychogenic, "though found to operate without dependence upon the viscerogenic needs were perhaps once subsidiary to the latter."⁵² Furthermore, though psychogenic needs (of which Construction, Dependence, Dominance, Aggression, Abasement, Succorance and Cognizance are examples) are common reaction systems manifested in all peoples, and though some of them may be innate, they are greatly influenced by cultural forms. The problem of innateness is not a central concern

to this acute observer. He pays more attention to distinguishing need-tendencies from each other and noting their directive effect on action patterns, and, in turn, the restrictive effect of action patterns on needs.

Even more important for the understanding of personality development, however, is the realization that needs become concentrated through learning on abstract or concrete objects, as well as on the self. Thus, baptized with the Freudian terms of positive and negative cathexes, McDougall's sentiments reappear. Here too, however, Murray would insist that while the personality is revealed in the objects it cathects, "especially if the intensity, endurance, and rigidity of each cathection is noted" in the individual's social situation,⁵² it is more important scientifically to know what needs are being expressed.

At this point, Murray introduces a new motivational concept to which McDougall seemed blind—something besides needs attaching themselves to objects and objects evoking needs. He is impressed by the "consistencies of connections" between objects, needs, and certain characteristic modes of action. Without this particular consistency of connection there would be no stable personality. Under the name of *need integrate*, Murray, therefore, conceptualizes a "relatively stable organization in the brain 'wherein' traces (images) of cathected objects in familiar settings become integrated in the mind with the needs and emotions which they customarily excite, as well as with the images of preferred modes."⁵⁴

A complete account of Murray's motivational concepts would articulate *subjectified* and *semi-objectified* needs as well as *attitudes*. It is more important here to note that this whole conception of need-functioning forces a radical change in the view of environmental stimuli. As Lewin had already suggested in his concept of "valence," the environment can no longer be simply the source of stimuli. It is to be understood as that aspect of the total field which is alive with threats or benefits to the individual. Rather than understanding the individual in terms of his environment, Murray sees the environment in relation to the "press," the relevance or irrelevance it has to the well-being of the person. Both "personality" and "environment" thus become the by-products of the individual's struggle to regain or establish need satisfaction.

Murray's view thus contrasts sharply with that of the school we are about to study, according to which the personality is essentially a product of the environment.

X. THE BEHAVIORISTIC AND ASSOCIATIONAL APPROACH TO PERSONALITY

Convinced that psychology can never take its place among the more exact physical sciences unless experiments are objectively controlled, quantitative analyses made, and results predicted, members of the behaviorist or objective school of psychology have found it necessary to belittle, deny, or disregard the validity of introspective observation and to sterilize psychology of all final causes.

A. OBJECTIVE ASSOCIATIONISM: LAURANCE F. SHAFER

1. Derivation of Motives. On this influential approach the sources of human activity are not instincts—conceived as universality of certain types of behavior and thus all too vulnerable—but inner physiological tensions and emotional excitements. The only innate drives are hunger, organic or tissue needs, sex, fear, anger and (after E. B. Holt) primary *adienage*. The "organism," attempting to reduce the tension set up by these drives, develops *habits* of removing the incitatory stimuli, or *motives*. These habit motives, such as mastery, submission, and sympathy, which McDougall considered innate, are not independent and autonomous springs of action, but function "only through the operation of the 'lower' fundamental drives of physiological and emotional tensions."⁵⁵

2. The Adjustment Process. The adjustment process begins when a drive is thwarted and ends when, as a result of trial and error or varied actions, a response is found which reduces the drives and thereby solves the problem. Is the response selected because it is pleasant? Shaffer rejects this Thorndikean thesis that "pleasure *per se* strengthens the neural connection and that pain weakens it," for such a notion is "entirely hypothetical," redundant, and empirically absurd, since pain is frequently an aid to learning.⁵⁶ Such mentalistic principles as pleasure and pain, or the "insight" of the Gestalt school, may be regarded as supplementary "*gross descriptions*" of adjustive learning, but how either can explain improvement is not clear.⁵⁷ Simultaneous conditioning, however,

can explain the selection of responses. Specifically, those responses are repeated "*that lead to tension reduction and the completion of motivated activity.*"⁵⁸ The cat in the puzzle-box does not learn to move the latch merely because of pleasure resulting, but because simultaneously with the exploratory adient movement toward the food the latch was released with consequent drive reduction.

3. Adjustment and Personality. The implications of this view for personality becomes clear when we realize that: "The personality traits of the individual are his persistent habits toward making certain kinds of adjustment rather than other kinds."⁵⁹ Again, traits are "residuals of the individual's . . . past tension-reducing solution of problems."⁶⁰ While Shaffer speaks of a "unified and continuous process of the growth of personality,"⁶¹ there is no theoretic attempt to explain why, in a receptacle of protoplasmic irritability, a "balanced outlook" should ever be effected. Shaffer does remark, incidentally, that integration may be a function of discriminative ability⁶² with resultant loss of inhibitory actions.

Thus it is, we are told, that "much unnecessary mystery to the development of personality characteristics"⁶³ is removed. One can see why Murray and McDougall were not satisfied by such resolution of mysteries. Far from being explained, the mysteries of purposiveness seem to be swallowed up or transliterated into scientific-sounding words like *tension* and *drive-reduction*, terms that have no concrete meaning unless purpose is insinuated.

B. SITUATIONAL ASSOCIATIONISM: EDWIN R. GUTHRIE

1. Trait Development. Guthrie, convinced that "in the strict sense all human behavior consists in muscular contraction and glandular secretion," believes that human personality "must in one sense be reducible to such activities of effectors."⁶⁴ We need not "speculate concerning the deeper reaches of the soul,"⁶⁵ or consider the personality as any kind of entity. For personality traits, like neatness and honesty, are the products of simple *movements* which have been combined into *grosser acts* in given situations. But no thoroughgoing understanding of a man can be achieved by *describing* his traits or acts, for "in any particular man the achievement of an act is completely dependent

on his acquisition, through learning, of a *specific and stereotyped* movement or set of movements for the accomplishment of the effect that defines the act."⁶⁶

2. The Associative Process. What fixes the correct response for Shaffer? The adjustment-process conforms strictly to associative learning. The individual, responding to a threatening situation, struggles until the movements appropriate to remove the threat appear. This set of threat-removing movements in that situation are protected from unlearning because in removing the individual from the threatening situation, they prevent new associations. Thus the appropriate movements are retained and the inappropriate eliminated. Once a habit is formed it becomes more characteristic of the individual than of the situation. Other similar situations evoke it and soon the individual becomes predictable in terms of his unique stereotyped habits.

Guthrie realizes that re-exposure to identical situations is impossible, and he is forced, with the rest of us, to predict in terms of "tendencies" rather than responses. It is not clear, however, how these mechanically associated responses, stereotyped to one stimulus-situation, can become tendencies in stimulus situations admittedly different. Assume that a tight collar led a man in a maiden speech to tug at it while talking, and that this mannerism has remained for years even though his collars have been larger. Is it true, as Guthrie says, that the movement elicited and guided by the pressure of the collar "now guides itself and can be started by odd components of the situation 'beginning a speech'?"⁶⁷ The similarity between "tight collar" and "beginning speech" calls for a meaning-analysis not forthcoming from such situational associationism.

Nevertheless, for Guthrie a repertoire of movement habits is hierarchized into act habits by selection and inhibition adjusted to a goal under the systematizing effects of institutions and culture. Personality is constituted by "those habits and habit systems of social importance that are stable and resistant to change."⁶⁸ Since general traits are not only harder to measure and "almost impossible to use after they have been measured,"⁶⁹ it is far better to restrict ourselves, in understanding personality, to analyzing the ways in which a neat person is neat in his situation, and especially to the skills he

has acquired in specific vocational and social adjustments.

3. Dynamic Associationism, A Synthesis? Determined that no soul-like, "theological" entity and no "mysterious" purposes should re-appear on the psychological stage, these objectivists have enthroned the ambiguous principle of association. The views recently expounded by Mowrer and Luckhohn⁷⁰ are all the more interesting if regarded as a counter-movement within association theory. They attempt a synthesis of unfavored psycho-analysis with learning theory, after the manner of Shaffer, but with Shaffer's implicit purposivism become more explicit. These writers insist that the moment the "advantage" of an adjustment is mentioned, associationism must become purposive. For them a man's behavior is the product not only of the total context in which it occurs but of primary tissue needs and secondary emotional tensions such as fear, anger, and love. These drives press for maximal integration or equilibrium; relatively stable, predictable habits result from the fixation of conflict-reducing movements. Personality is formed as these habits merge into an "organized, adjusting, behaving entity."⁷¹

XI. THE APPROACH FROM STATISTICAL EMPIRICISM OR FACTOR ANALYSIS

A. *The Task.* Another attempt to deliver psychology from the sands of introspection and set it upon the rock of objective quantitative measurement is that known as Factor Analysis. Objective psychology, aided by mathematics, brought with it performance tests. Further aid from statistical procedures made it possible to intercorrelate many tests taken by the same subject and thus clarify both the problem of the individual differences and the structure of personality. For, as Charles Spearman, the leader of this movement, saw it about twenty years ago, the assumption that mental functions like memory are unitary is unsupported. Does the memorizing of details involve the same "memory" as the remembering of principles? Is the cheerful person cheerful in all situations? The answer should depend on objective and adequate scientific justification.

No account can be given here of the different correlation techniques and factorial methods used by Spearman, G. H. Thomson, K. J. Holzinger, C. Burt, W. Stephenson, L. L. Thur-

stone, R. Cattell and many others. Common to all factor analysis, however, is the assumption

"that performance in any field such as the cognitive, depends neither upon one undifferentiated ability nor upon a completely chaotic conglomeration of separate abilities. Rather it is assumed that cognitive ability consists of a number of different factors, traits, faculties, or powers, each of which is elicited by a variety of different tests or problems."⁷²

In essence, then, the factor analyst studies the intercorrelations between the tests taken by his subjects, and notes the common factor discernible in the performances on various tests. "All that is assumed is that a cause or group of causes, however produced, acts as a functional or operational unit."⁷³ Strictly speaking, therefore, a factor is a mathematical abstract indicating the presence of some common determinant among the variables studied. Factor analysis is a simpler level of analytic description than the tests; at a deeper level are the many genetic and experimental constituents of the factors.⁷⁴

It should be clear that the factor analyst as such has no new source of information on the psychological nature of the factor. He may hope, as Thurstone does, that one day the factors will be identified "in terms of different aspects of the physical system that constitutes a person,"⁷⁵ but all such preconceptions or interpretations of statistical results will not enjoy a mathematical, objective basis, but will depend on the psychological acumen of the analyst. It is the conviction of Spearman, reaffirmed by Wollfe after his excellent survey in 1940, that truth will be approached only if the imaginative and the clinical accounts of factors supplement each other.

B. *Early Discoveries.* Historically speaking, factor analysis was so productive in dealing with cognitive traits that the technique was applied to motor and mechanical abilities and then, more recently, to the problem of basic personality traits.⁷⁶

Spearman's experience with the Theory of Two Factors will illustrate the basic procedure. He noted upon analysis of scores of dissimilar mental tests, a *general* factor *G* common to all, and another *specific* factor *S* varying with each test. While *S* varied irregularly with the *S*'s of others, *G* kept the same proportionate relation. The more *G* was found in any ability, the less

S, the latter seeming more dependent on organic powers, past experiences, non-cognitive aptitude for the given task, and sheer retentiveness. This hypothesis, drawn from limited observations, was subjected to an extensive investigation at Chicago. Ninety-four tests were administered for abilities ranging from creative imagination, perception, memory, and attention to speed of tapping. The analysis of these tests revealed the general factor *G* in every cognitive ability, save retentivity, though in different degrees (e.g., 5 per cent in tapping, 65 per cent in generalization).

So much for mathematical analysis. The next problem, which "leaves room for widely divergent views,"⁷⁷ is: What is the nature of *G*? Lashley, the physiologist, suggested that *G* measures some "mass action" of the cortex, and Thorndike changed his earlier atomistic view of mind when he suggested that *G* was "some unified, coherent fact in nature" independent of non-intellectual factors.⁷⁸ Spearman himself tends to think of it as measuring "general energy" supplied by a large portion of the nervous system.

C. *Factors of Personality*. It was B. J. Webb who extended factor analysis significantly to non-cognitive ("orectic") traits. His study of character not only confirmed *G*, but analysis of evaluations of personal and social moral traits yielded *H*. "Its nature is best conceived . . . to depend upon the consistency of action resulting from deliberate volition, i.e., from will."⁷⁹ But once more, "the interpretation is extremely open to controversy and to progressive improvement."⁸⁰ It is worthy of note at this point that the studies made by Hartshorne, May, and Maller on the generality of character-traits such as honesty and persistence (characteristics of *H*), when subjected to factorial techniques by Maller, indicated the presence of the general factor *H*, a conclusion in direct opposition to the earlier non-factorial analysis of the data.

The application of factor analysis to other aspects of personality has indicated over fifty factors. Major agreement, as Wolfe's 1942 study reveals, is found in *C* or cleverness, *S* or sharpness, *F* or fluency of mental activity, *D* or mental depression, as well as factors such as self-confidence and hypersensitivity respectively.⁸¹ Thurstone, attempting to interrelate personality with perceptual experience, suggests "a factor

that is conceived with facility in perceptual closure which is distinct from considerations of acuity," and several others.⁸²

D. *Appraisal*. There can be no reasonable objection to organizing the results of human performance more economically and suggestively. It is only when considerations of mathematical convenience and parsimony dogmatically guide interpretations about the psychological nature of the unit involved, or lead to the substitution of factorial *analytica* for psychological description that protest must be vigorous. For mathematical procedure must be guided by psychological conceptualization of the traits involved, and in the end, if factors are to have psychological meaning, they must be interpreted in terms of psychological functions and what is otherwise known about personality. As Thurstone said,⁸³ factors may give a crude first map of a new area, but the concrete highways will have to be laid out with our best psychological insights. After all, not the skeletal bones of abstracted factors but the unique organization of a personality which embraces them is our concern!⁸⁴ Indeed, careful analysts like Burt and Spearman not only bemoan "statistical zealots who accumulate 'masses of figures that remain psychologically senseless,'" but remind us that "the very development of statistics is showing with increasing force where their own brief authority must come to an end."⁸⁵

XII. THE GESTALT AND HOLISTIC APPROACH: KOFFKA, LEWIN, AND ANGYAL

A. *Implications of Holism*. Standing solidly on empirical studies of perception, learning, and thinking, Gestaltists have carried their battle against the mechanical associationism and behaviorism into the field of personality. Andras Angyal,⁸⁶ expounding clearly the logic of this approach, has recently insisted that organism and environment are not two independent ultimates which interact. They are, rather, two distinguishable tensile poles within a reality-field. But while hostile to atomic "mechanistic" explanations, Gestalt theorists shy away from positive teleology. Indeed, it may be said that they have substituted for an atomistic mechanism a non-purposive, mechanistic whole whose intrinsic order determines the needs, nature and function of the parts.⁸⁷ Thus trends, tensions, needs, and directional tendencies relieve the

mysteries supposedly implicit in propensities. For example, Angyal attributes to the organism an inherent "self-expansive tendency,"⁸⁸ or an "undifferentiated trend toward increase of autonomy." But he discards the word "teleological" for "directional" to describe this view, since he fears that teleological activity involves reaching a goal,—though he admits that "the much criticized 'purposivists' almost never have used such a rigid and static concept of teleology."⁸⁹ At any rate teleology as well as mechanism is rejected.

The Gestaltists join purposivists, nevertheless, in rejecting stimulus-response psychology. But they add their own touch. An individual responds not to an environment, but to the environment *as conceived by him*. Thus Gestaltists distinguish the behavioral or psychological environment from the inferred or geographical environment. Thus, as Angyal says: "The concept 'External world' must be clearly distinguished from the concept 'environment.' The external world can be called environment only when and in so far as it is in interaction with the organism."⁹⁰

The Gestalt master-key is used to unlock the mind-body mystery also. K. Koffka and K. Lewin accept the isomorphism developed by Wertheimer and Köhler. On this view "any actual consciousness is in every case not only blindly coupled to its corresponding psychophysical processes, but is akin to it in essential structural properties."⁹¹ Not even this doctrine is holistic enough for Angyal who is convinced that both mental and physiological events are functions of a psychophysically neutral or holistic unit (Stern). "Neural processes cannot produce ideas, and thoughts cannot make muscles contract, but the total organism, the person, can do both."⁹²

B. Holistic Personality Formation. Restricting ourselves to relevant contributions of Kurt Koffka and Kurt Lewin, we shall note how the concept of personality emerges from this ground of holism, behavioral environment, and isomorphism.

An Aristotelian would view a personality as an individual exemplification of a class, but not Lewin! He sees personality developing from the present convergence of field forces. Unlike Murray who emphasizes the past, or Allport who focuses on unique and orderly patterns within personality, Lewin keeps his eye on the present

dynamic balancing of personality-environment forces. As Koffka says, the personality, or Ego, "is neither a point, nor a sum or mosaic of drives or instincts."⁹³ It is the development of the organism, a "peculiar kind of system" which maintains its own orderly equilibrium and spatio-temporal unity as it evolves and interacts with the world.

Indeed, were there no Ego and "its attention and attitudes," there would be no behavioral world and no "external" world. The Ego is the nucleus of spatial dimensions. Furthermore, it can expand to include one's clothes or shrink to exclude one's body, or thoughts, or emotions. The boundaries of this elastic Ego are not predetermined but variable. This variability does not mean, however, that all processes or things are equally fit for incorporation within a specific Ego.

However, if the Ego does have a variable "membrane," what are "the forces that at this moment keep the Ego segregated"?⁹⁴ Koffka candidly admits ignorance on this question and goes on to explain why some processes are incorporated into the Ego and some not. Were it not for the spatio-temporal coincidence of visual and kinaesthetic impressions the infant could not weld his bodily Ego together in the second year. Then the needs which well up and persist within this Ego-system become foci of organization. While the Ego is formed on the conscious level, the more stable developments probably persist below the conscious level as what the Freudians call the "unconscious." It is this "stable organization of the Ego-system which prevents it from being changed by every new influx." Still, while thus anchoring and "directing" growth the Ego itself is always going somewhere and its stability "must, therefore, always be seen in relation to the direction in which it is moving."⁹⁵

This Ego clearly squints! It is both the incorporator and incorporated, both knower and known, wantor and wanted! This squint pursues Koffka and Lewin every step of their way. Their concern for a concrete account of personal unity in terms of field theory seems to blind them to the theoretical presupposition of belongingness—an indivisible active agent—which incorporates the Ego in the first place. Aristotle may have lost the individual to the class; Koffka and Lewin lose him to the field. Would not the intrinsic unity of a purposive, knowing-wanting

self, which develops an Ego, provide the force which keeps the Ego segregated?

C. *Internal Personality Structure.* To the genetic, longitudinal account of Ego-formation must be added a cross-sectional account. The fact that the incorporating boundaries of the Ego are variable indicates that the Ego is a network of sub-systems whose inner tensions activate it. Thus, in order to explain the conclusion of Zeigarnik's famous experiments, in which the subjects remembered incomplete tasks better than the completed, we must suppose that the tensions set up by each task belong in relatively independent, insulated sub-systems. The systems for completed tasks are more stable, their tensions having been released. But the duration of unfulfilled tensions become particularly strong "if the tasks of the experiment were in communication with the Self."⁹⁶

We realize, accordingly, that, for Lewin, within the structure of the *developed* Ego (not the developer of the Ego), a "permanent sub-system" has been incorporated which represents the "real needs" and ambitions of the individual. "The Ego has a core, the Self, and enveloping this core, in various communications with it and each other, are other sub-systems comparable to different layers, until we come to the surface, which is most easily touched, and most easily discharged."⁹⁷

The sketch thus presented does not begin to do justice either to Koffka's intricate discussion or to Lewin's symbolic, topological mappings of the personality into an inner-personal region with its central and peripheral strata and motor regions. It must suffice to emphasize that "each dynamized, psychical system does not have clear communication with every other,"⁹⁸ though frequently the satiation of a need in one system produces satiation in a functionally adjacent one. The action that ensues always depends on the intimacy of intercommunication at a given time in a specific total situation.

XIII. THE PERSONALISTIC APPROACH: STERN AND ALLPORT

It should be clear now that the psychology of personality has been very sensitive to the assumptions, methodological techniques, and the new discoveries in the physical and social sciences. The human personality has been stretched and shrunk, measured and classified,

injected with "forces" and reduced to nerves, muscles, and glands, all in the name of science, which after all is itself a production of human personalities. It has seemed more important to be true to science than to personality. Time and again the approach and answer to problems have depended on whether the psychologist was more concerned to keep the totality of human experience before him and test his insights by the best scientific procedures, or whether he allowed the norms, procedures, and assumptions of science to determine his approach to personality. Adequacy to all the psychological data and adequacy to "science" are in constant conflict. Thus a scholar like C. L. Hull,⁹⁹ in order to guard himself against what he regards as the fatal, anthropomorphic, teleological explanation to which many psychologists unfortunately succumb, goes through a purifying ritual of regarding "from time to time, the behaving organism as a completely self-maintaining robot, constructed of materials as unlike ourselves as may be." Such is the price personality is sometimes called upon to pay as its corpse is glorified with the swastika of scientific objectivity.

A. William Stern

1. *The Person as Convergent.* Stern's personalistic psychology is a protest against this "scientification" of psychology, and the resulting "mechanization of spiritual life."¹⁰⁰ For Stern, "man *qua* person is a unity, indeed the primordial and most pervasive unity in the range of the experiential world . . ."¹⁰¹ He resists, therefore, every attempt to dissect, or type, or reduce "genuine individuality," as distortions of that "something indivisibly singular, a personality."¹⁰² The person is a "unique and self-sufficient *unitas multiplex*, whose activity as a purposive function is directed toward self-preservation and self-development."¹⁰³

Stern expounds his doctrine of a psychophysically neutral person as a "radical synthesis" not only of the mind-body problem, but also of the exclusive dualisms of consciousness-unconsciousness, of teleology-mechanism, and heredity-environment. Thus, consciousness occurs only when the smooth, vital flow of psychologically neutral ongoing is interrupted. The person, "the most genuine whole of all" is always a mixture of constraint and feeling . . . *Gestalt and Un-*

gestalt,"¹⁰⁴ and not a homogeneous Gestalt. Indeed, "*Keine Gestalt, ohne Gestalter*"!¹⁰⁵

Furthermore, personal development is not a mechanical interchange between the person and the environment. The person's "purposively inclined but not yet unequivocally confirmed tendencies" are given greater definiteness within the environmental situation. But the environment acts not as a coercive field "under whose pressure the person is cast into a certain mold." Its stimuli, rather, are "raw materials, points of attack, and collaborations" of the inner purpose.¹⁰⁶ In fact, "the interaction, the 'convergence' of these two groups of conditioning factors is the occurrence of the real person."¹⁰⁷ Stern thus saves the unity and resiliency of personal activity without denying the effect of the environment.

2. Motivation, Will and Character. Indeed, personal development involves a "constant, never-ending task of realizing values"¹⁰⁸ which the environment suggests (introjection). This process in fact actualizes inner strivings. For Stern, the "goal-structure" of the person embraces not only implicitly purposive reflexes, but innate, vague, directional dispositions. He recognizes three types of vital urges,—those for self-preservation, those of self-development, and elementary social drives which man shares with animals. Unlike many contemporaries he boldly insists that in man there are drives "toward intellectual, ideal, and cultural objectives." These cognitive and creative drives, to be sure, presuppose personal maturity, but they must not be overlooked simply because they do not occur "in the form of bare impulsiveness."¹⁰⁹

Stern would have little sympathy with the customary bony, parsimonious lists of tissue and social needs. For he cannot bridge, as the other psychologists do, the gaping chasm between these wants and the artistic, scientific, and religio-ethical needs by uttering the magic words "conditioning in a society." For Stern the "higher" are not only not derivable from the "lower." The supposed development from the lower could not be effected without the co-presence of the "higher"! Nevertheless, Stern also sees that all of these vague, flexible directional tendencies become more articulate when they meet resistance and become *needs* for future fulfillment, or the fighting core of personality.

Finally, while most psychologists, including McDougall, would stop here and consider human will the product of character formation, Stern's concern to "save the phenomena" leads him to make a careful analysis of will.

At the simplest level we experience will when we *sustain* an obstructed desire, say, to pick up a book. But the experience of will is more articulate when we choose between wants and general principles, and more "intellectual" when we prosecute a well-laid plan. Unable to reduce will to conation, Stern contends that it is interwoven with, and supports, conative life! When needs whose goals are too remote cannot be satisfied directly, will acts to close the gap between striving person and denied result. In willing the person "has a peculiar consciousness of self-activity."

"The acme, however, comes in the concentration, at a *definite* instant, of the experience of being able to act, into a direct experience of *acting* 'Now I will . . .' This *onset*, which eludes closer inspection, is the core of every act of will."¹¹⁰

And so intrinsic to personal activity is this Jamesian *fiat* that Stern exclaims, "*Volo, ergo sum*,"¹¹¹ It should be superfluous to add that intellect, emotion, and will are phases of indivisible personal activity.

Character, on this view, becomes the person's "own monumental achievement"¹¹² gradually selected and developed in "convergence" with the value-environment. It is at once the product of willed learning, and the matrix in which many "settings of will," lasting and temporary, take root. What other psychologists call attitudes or traits become for Stern "readiness for acts of will of a definite kind and direction."¹¹³ And Stern, with McDougall, anticipates recent Ego psychology by pointing out that the hierarchical structure of character is in the last analysis "produced by the incorporation of self-regarding goals and outside goals."¹¹⁴ At this point Stern acclaims the "important progress toward this goal . . . in G. Allport's *Personality*."

B. Gordon W. Allport

1. Emphasis on Uniqueness. The personalistic viewpoint advocated by Stern has found learned,

empirical, and original support in G. W. Allport's writings, especially in his treatise: *Personality: A Psychological Interpretation*, 1937. Psychophysical parallelism is substituted for Stern's psychophysical neutrality, but the "undivided personality," with its uniqueness, its basic continuity, its unity and multiplicity are never forgotten by this scholar. Impressed by the insistence of Dilthey, Klages, Jaspers, Spranger, and Stern, that individuality be taken as the psychological datum, he proposes that every hypothesis, *Verstehende* or not, be submitted to every conceivable empirical test and procedure, "case-histories and diaries, ratings, biographies, correspondence, introspection, questionnaires, clinical records, psychoanalysis, clues from expressive behavior, or drama and fiction,"¹¹⁵ as well as experiment and intuition.

Far from yielding to the arbitrary conviction of "high science" that the individual must be considered as an example of generalized categories, Allport bends every energy to reveal and explain the lawful patterning within individual life. A psychology of the concrete interrelated personality structure cannot, as Klages once said, be built "out of the permutations and combinations of the universal characteristics."¹¹⁶

2. Purpose and Motivational Given. While Allport, like Murray, Koffka, and Angyal, would immediately reject thoroughgoing mechanism, he would seem to agree with Kempf (and Shaffer and Guthrie) that in early childhood there is "no need to postulate an elaborate system of latent purposes,"¹¹⁷ and that behavior is stimulated by innate, vegetative "pushes." As a matter of fact, however, he would object to any "sharp antagonism" between "pushes" in infancy and "pulls" in maturity. For he believes that the "organismic position" has succeeded in overcoming the teleology-mechanism antithesis by redefining both purpose and mechanism and "reconciling them within the new concepts of structure and system."¹¹⁸

For Allport, then, the child, uniquely given a physique, temperament, and general intellectual capacity is motivated to reduce segmental tensions such as hunger, strain and other physical needs. Unlike Shaffer and Kempf, however, Allport sees that:

"It is all too easy to say that the primitive organic tensions become *conditioned*, and by this bit of verbal magic to think that one has

accounted for all the motives of the adult personality whose desires include not only nutritional and sexual satisfaction but likewise fine music, rare books, and the answers to puzzling problems in science, politics, and theology."¹¹⁹

But where Stern had supplied roots for such non-organic tendencies (especially in the drive for intellectual activity), Allport cannot accept any generic list of propensities, rich or poverty-stricken, and this for two main reasons.

First, similarities in basic motivation alleged by hormic theories can be explained by the fact that "similarly constructed individuals living in similar environment, influenced by similar culture, *would* develop similar goals and employ similar methods of obtaining them."¹²⁰ Bertocci wondered how a similar culture could exist in the first place unless human beings are also given similar non-physical drives in a similar physical environment.¹²¹ Allport replied "that the universal features in cultural practices all over the earth appear to be too few in number to argue from them to common instinctive causation."¹²²

Second, he believes that "an elaborate process of learning and growth intervenes between the organic wants of infancy and the cultural wants of adulthood, involving all manner of linguistic, imaginal, and rational factors that ultimately transform the segmental cravings of infancy and innate propensities into desires having no longer any functional connection with them, but holding in their own right an autonomous place in personal life."¹²³

The process here referred to is that of *functional autonomy*, but the issue intrinsic to it is that of ontogenetic emergence. Can pre-social vegetative drives be transformed into social, aesthetic, and spiritual desires? Allport, agreeing that the psychology of learning has not adequately considered this particular problem, is forced to lean on the principle of ontogenetic emergence to support his conviction that early propensities (given such) are not merely altered, as McDougall, Murray, Shaffer, and Stern would hold, but "*supplanted*" by adult motives.¹²⁴ The problem at this point enters the realm of metaphysics, where we must leave it, but not without the realization that explanation of personal continuity is at stake.

3. Personality Development. The adjustive responses of the plastic infant take on selective

consistency by six months. When conditioned reflexes are integrated into habit-systems and these habit-systems are embraced by traits, personality begins to take shape. The growth of self-consciousness is fundamental to the development of personality for in it is reflected the individual's concept of his world, his introjection of social norms, or his *self-esteem*. Maturity brings with it an ego-ideal, "the plan that the developed personality is able to evolve for defeating, by transcending, both the unsocialized urges of the Id and the dullness of the Super-Ego, leading thereby to a new level of personal freedom and to maturity."¹²⁵ Allport hammers the thesis that a person's behavior is the product of his *present organization*; he is anxious to avoid excessive reliance on the environmental situation (Lewin) or on the past experience, especially when interpreted psychoanalytically (Murray).¹²⁶

4. Inner Personality Structure and Traits. Allport, we have seen, rejects any suggestion that the unique personality is a variation played on central, general themes. Adulthood sees "greater and greater divergences from the relatively standard pattern of infancy,"¹²⁷ thanks to functional autonomy. However, to account for relatively stable but unique personality, a concept must be developed which accounts for the continuity, uniqueness, and variability of personality. The definition of a trait suits these requirements. A trait is "a generalized and focalized neuro-psychic system (peculiar to the individual) with the capacity to render many stimuli functionally equivalent, and to initiate and guide consistent (equivalent) forms of adaptive and expressive behavior."¹²⁸

This conception of a generalized trait has had to battle with an opposing view which dominated the American scene. According to this prevalent, earlier view, traits (honesty, neatness, self-control) are unempirical speculations, especially since certain experimental findings force the conclusion that specific habits alone are the units of personality. Furthermore, we cannot predict what an individual can do in a given situation, unless we know how his past experience has linked his movements to that stimulating situation; to predict his behavior in other situations is always a hazardous undertaking, since a person is not neat as a man but neat in that situation and in this insulated way. "It seems to be a fair conclusion from our data

that honesty and deceptive tendencies represent not general traits, not action guided by general ideals, but specific habits learned in relation to specific situations which have made the one or the other mode of response successful."¹²⁹

Allport is not slow to underscore the quandary we would be in if this doctrine were taken seriously in practice. Do we not expect a man to be trustworthy in situations unlike the one in which the "habit" was built? The common sense in the theory of general traits is supported by experimental findings. For example, to suggest that inconsistency in the honesty of children is an argument for specificity is to overlook the fact that children have *other* traits, such as bravado or timidity, which keeps them from consistent practice of honesty as a trait. Indeed, personal consistency in conduct will never be adequately discovered by statistical methods which compare individuals only for a common trait.

In any case, this theory, which would explain consistency of conduct by partial identity either in the environmental situation or between the habits themselves, stands up only as long as the exact nature of the supposed common elements goes unprobed. Careful problem-suited experiments indicate over and over again that "identical elements in themselves have no power to effect transfer. Only when a general principle is understood as applicable to two or more fields does training carry over to the others."¹³⁰ Nay, identity and similarity are not objective factors stimulating an individual, for he must see identities and similarities as being functionally equivalent to him. Thus, to a loyal American, buying bonds, giving blood, reducing house temperature, writing V-letters, and sending his son off to war are functional equivalents because of his trait of patriotism.

Traits, to be sure, "are never directly observed," but if we are to give any plausible account of the continuity and consistency which pervade separate actions, "they are of necessity inferred."¹³¹ Traits, furthermore, function either as driving motives, or as merely directive or stylistic manners. Thus a man motivated by honesty may express this trait stylistically by brutal frankness or by diplomacy. It becomes clear that while a trait focusses and mobilizes lesser habits, skills, and attitudes, it overlaps, interpenetrates, and clusters with other traits. If a personality is sufficiently integrated, it will

be marked by the influence of a *cardinal* trait (or master-sentiment) in one's life, or at least of *central* traits.

We already have noted the part played by self-esteem and the ego-ideal in the organization of the personality. Traits represent the concrete pattern actualized within a personality whose reach usually exceeds its grasp. In recent writings, Allport has been impressed with the fact that "under conditions of ego-involvement the whole personality manifests greater consistency in behavior,"¹³² and that men are active, rather than re-active, participants socially to the degree that their *egos* are involved.¹³³ This ego, it would seem,¹³⁴ is that variable portion of the personality (cf. Koffka) with which the individual identifies his central values (traits, sentiments, ideals). It thus becomes at once a unifier and catalyzer of psychological capacities and energies, and the resultant of such mobilization. It would certainly involve cardinal or central traits, but its nature and extent is not static, being as it is a non-separable phase of the total personality. Apart from this important function, however, the ego plays a very important theoretical part as anchorage to the "new and somewhat radical principle of growth"¹³⁵ which is "altogether basic for the psychology of personality,"¹³⁶ namely, *functional autonomy*.

5. Functional Autonomy and the Ego. Convinced that a psychology of personality must be post-instinctive and avoid the suffocating restrictions of biological dynamics, Allport advocates functional-autonomy to render intelligible the process of human development.

"Somehow in the process of maturing the manifold potentialities and dispositions of childhood coalesce into sharper, more distinctive motivational systems. *Pari passu* with their emergence these systems take upon themselves effective driving power, operating as mature, autonomous motives quite different in aim and in character from the motivational systems of juvenile years, and very different indeed from the crude organic tensions of infancy."¹³⁷ . . . The dynamic psychology proposed here regards adult systems as infinitely varied, and as self-sustaining, contemporary systems, growing out of antecedent systems, but functionally independent of them. . . . Each motive has a defi-

nite point of origin which may lie in the hypothetical instincts, or, more likely, in the organic tensions and diffuse irritability. . . . But as the individual matures, the bond is broken. The tie is historical, not functional."¹³⁸

Allport is high-lighting the fact that learning often transforms (he would say supplants) prior motivational energies, that earlier means do seem to become ends in themselves or new bases for motives. But another issue faces Allport besides that of the emergent magic whereby aesthetic and social needs spring from vegetative urges. Bertocci has suggested that if mechanisms do cut loose not only from the original but also from all innate purposive drives, the unity and longitudinal consistency of any acquired personality is no longer intelligible. This concern for the empirical and functional continuity of personality led Bertocci to ask for a unity-preserving account of the change from one motivational system to another, if persistent underlying drives are denied. Why are different and successive motivational systems functionally equivalent? What guides selection and what is responsible for discontinuance?

Allport clearly answers: "I regret ever implying . . . that motives fly off at a tangent and have no bedrock anchorage in the satisfaction of the ego . . . Motives, I contend, may be autonomous in respect to their origin but never in respect to the ego."¹³⁹ All motives "imply some form of ego-satisfaction,"¹⁴⁰ and trait-constancy ultimately depends on the capacity of a trait to satisfy the "living system of interdependent motives" which, after all, constitute the organism. "Hence it comes about that evolving motives reconstitute the ego even while dependent upon it for their viability."¹⁴¹

There can be no doubt that the acquired ego does indeed provide a better basis for "novel" motives and their selection. But as already has been suggested elsewhere,¹⁴² the ego itself is a selected adjustment, it is itself functionally autonomous of primitive drives. H. Cantlil and Allport would agree that the ego, in the main, represents the interiorization of cultural values, but what is needed is an interiorizer, a selective agent-self (or what we called above, the psychological self) to choose among the adjustments and values which finally constitute the ego. Such a self, making its way not only among

established cultural values, but especially among those within its given range of abilities, temperament and needs, gradually selects the ego seemingly adequate to it, and changes it, insofar as it can, when it sees fit. The ego, a joint-product of the adjusting, knowing, wanting self, does indeed constitute a derived motivational pattern of values *within the total personality*. But ultimate anchorage for it would be in the evolving, time-binding, psychological self and its basic needs and abilities.

SUMMARY

We have seen how the empirical psychology of the concrete individual gradually emerged from philosophical concerns about the nature of unity and continuity, from terminological confusions, from the grip of typologies and generic constitutional elements, such as glands, instincts, drives, reflexes and factors. The inviting "mask" of personality has indeed brought many suitors, in the name of common-sense, the arts, religion, philosophy, biology, mathematics, sociology, physics, and finally "scientific methodology." But none of the suitors has won her, for they have sought to ensnare her by their formulae rather than respect her for her many-sided uniqueness. Receptive to the disinterested attention of each discipline, personality still defies attempts to partition her or to reduce her to a mere product of forces, or entities, or behavior, or fields, or confining procedures.

It may be, as MacKinnon has said, that: "A field theory of personality which sees behavior and personality as functions of a total field of which they are sub-parts is the form of theory which today seems best suited for the conceptual representation of personality."¹² But, on the other hand, it has seemed to the present writer that the intrinsic uniqueness, self-determination, and purposiveness of personality are not sacrificed as much if we take the point of view that the central feature of personality is the knowing-wanting *unitas multiplex*. This psychological self, which satisfies its needs according to its abilities within a social-physical field, gradually develops those enduring traits which in their interpenetration constitute the self's personality, a complex mode of adjustment vulnerable both to inner demands and outer exposures. The personality is not the product of an ambiguous field of forces, but represents

what a given unique self has created out of the forces and opportunities open to it in its rapport with the world.

"culture." When this point of view is taken, the student is interested in those aspects of personality which are common to all those who share a common culture; deviations and variations are of interest only as they serve to further define the "national or cultural character," or "basic personality structure" distinctive of the particular culture. Individuals are studied as samples of a type of behavior which is recognized as systematic. Thus the extreme emphasis upon personal bravery and warlike character among Dakota Indians, and the institution of the berdache under which young males who find the emphasis on bravery too great to bear, assume women's clothes and occupation, will be viewed together as data on an aspect of Dakota character which includes a demand for bravery and a possibility of refusing to meet the demand. The actual distribution of behavior types in which most young men accept the demand and only a few reject it, will also be taken as descriptive of the "cultural character," and as one method of comparing it with those cultures in which there is a single and less exacting demand for moderate bravery with minor deviations towards greater or less bravery. Similarly where types of culture character are recognized in which there are several possible expressions of some basic emphasis, such as extreme prudery and institutionalized prostitution, fastidious personal cleanliness and great tolerance towards public lack of sanitation, or great public cleanliness and lack of personal hygiene, extreme brutality combined with an exquisite appreciation of aesthetic detail, a controlled unemotional religion combined with societies of intense witchcraft behavior, etc., such contrasts, whether found to run through the behavior of the same or different individuals, will all be regarded as data on central themes of a varying number of facets and with varying types of emphasis. The task is to concentrate upon and describe those regularities which may be ascribed to social inheritance as distinguished from those which may be referred to individual innate characteristics (*temperament or constitution*) or to the accidents of the personal, idiosyncratic life history. Man's basic mammalian nature is, however, systematically included in any discussion of cultural character in the premise of the "psychic unity of mankind." Cultural differences are delineated against a common humanity.

PERSONALITY, THE CULTURAL APPROACH TO.—The cultural dimension of personality may be looked at from two points of view. We may emphasize those aspects of personality which can be systematically referred to the regularities of behavior in the society within which an individual is born and reared, or to which he or she is exposed for appreciable periods of time, which taken together we call

The second approach to the cultural dimension comes with emphasis upon the types and varieties of personality *within* a culture when emphasis is laid not upon innate individual gift, nor upon individual history, but upon the way in which the institutions and formulations of the culture provide for such varieties. The recognized gamut of individual differences, the extent to which intelligence or beauty, strength or skill is singled out, approved, or completely discounted, is culturally defined. The same detail of physiognomy which among one people may entitle one to a position of beauty, may be classified as ugliness in another culture and ignored altogether in a third. One culture may have a concept of "the artist" which includes a destiny based upon having been born with the umbilical cord around one's neck, a second may push all individuals with talent into an artist-craftsman group, a third designate as artists only those who combine talent and deviance, a fourth make skill and artistry a function of clan or family membership. One culture may distinguish between the "serious" and the "naughty" so that people insist upon classifying all individuals in one group or the other and demand and get differentiated behavior from them, another may emphasize as an essential a vulnerability or lack of vulnerability to sorcery as shown by illness. One culture may demand a subjective and visionary experience from every male child and condemn to social unimportance those who fail to achieve such an experience while another may place such a slight premium upon any type of subjective experience that those who report such experiences are voted insane or possessed. Within cultures which recognize sexual inversion as a type of behavior to be expected and either approved or disapproved, such behavior occurs much more frequently than in those cultures which do not recognize such a possibility.

So, it is possible to consider personality culturally from this standpoint also, asking not what are the regularities which characterize every person who shares this culture, but what provision does the culture make for the development, the institutionalization, the maximization or minimizing of differences, whether those differences may be referred to heredity—as in the case of shape of nose or type of hair—to accident—as for instance when a child who has been scarred from a wound is regarded as

unfit for religious office,—to socially provided special training, as when certain individuals are selected to undergo a different education from their fellows, to physiological status,—as when women past the menopause are permitted male license, to social status determined either by heredity or social experience, or to various arbitrary combinations of these as for instance when personal bravery is approved in a man of rank and disapproved in a commoner, or when mathematical ability is rewarded in a male and ignored in a female. Although in any human group a large number of differences will be found which may be referred to temperament and constitution, and to historical accident, whether these differences are socially significant aspects of personality recognized by the group and by the individual who displays them, is dependent upon the culture. Even if differences between individuals are recognized they may be placed in an entirely different context, as when a European might say of a Samoan girl, "She has a lot of intensity," to be answered, "She's deaf," or of a Iatmul woman, "What a violent temper she has," to be answered, "She's a widow," or of an Arapesh man, "What a malicious nature he has," to be answered, "He has ringworm." Conversely, where an impartial observer might say of a student in a Middle Western school, "She has social status and so is popular," student vote might insist that she was the most beautiful in the class, even in opposition to American standards of beauty. The most striking deviations from statistically usual behavior, such as inversion, epilepsy, subnormal mentality, polydactylity, musical or mathematical virtuosity, a rare singing voice, may go completely unrecognized, unpunished and unrewarded, while details of a quite different order, such as day or hour of birth, may be made the basis of a system of education or special privilege which differentiates one individual from another to a very great extent.

In most instances when students speak of the cultural determinants of personality, they tend to think of uniformities in the behavior of those who share a common culture rather than regularities. So a tendency to speak volubly and with emotion will be referred to Italian culture, but the extent to which some individuals speak very little and others a great deal will be referred to "individual differences" ignoring the

fact that range and contrast, even sharp contradictions among the behavior of individuals sharing the same culture are also "regular" and referable to the culture. Differences between the expressive and free behavior of lower-class Negro Americans and the restrained behavior of middle and upper class Negro Americans may all be referred to the class standards and race attitudes of American culture as well as "individual differences" between the expressive lower class Negro American who laughs loudly in a subway train and the quiet, well-bred young Negro lawyer who sits across from him. Even the extent to which individuals of one type or another may become involved in changing their class position is also culturally regular. So in a working class group where great vigor and lustiness are rewarded it may be the puny who aspire to changed status while in a group upon whom malnutrition and disease have laid their stamp, only the exceptionally vigorous may have the necessary physical qualifications for changed social status. Perhaps the simplest illustration may be found in the way in which men and women do their hair in present-day America, the men with a high degree of uniformity, the women with greater emphasis upon conformity to rapidly changing fashions and distinctiveness within the fashion. Looking at a mixed group, the men's appearance is much more uniform than the women's. Each type of behavior is to be referred to the culture, but in the case of the women the culture has institutionalized a degree of individuality; in the case of the men, non-individuality has been emphasized. Once the concept of "regularities" rather than "uniformities" is fully accepted, the confusions which so frequently arise between what is cultural and what is individual is dissipated, and we can distinguish instead between looking at behavior "culturally" and so stressing the regularities and looking at behavior in terms of "individual differences," stressing the innate and the idiosyncratic. The student of individual differences may wish to choose culturally regular behavior within which the allowance for individual variation is small so that very minute differences are significant—as would be the case in any attempt to use male haircuts as data, in our society, or large, if male hair arrangements among the Usiai of the Admiralty Islands were the subject of study.

Even the extent to which differences in life

history experience will become significant in the life of an individual, has a cultural component. Some cultures permit individuals to relate themselves to a line of inheritance, others to a series of achievements or failures in the educational system (as in traditional Chinese society). Today under the influence of Freudian psychology, individuals are culturally permitted to phrase current success or failure in terms of the treatment they received in early childhood. In some cultures, as for example the Iatmul, the sense of personal differentiation of the self is so weak that a youthful informant asked to relate his own life history will pass his present age and continue to describe a culturally approved career line which he has not yet lived through, without any sense that this life is not yet his because he has not yet lived it. In cultures, like Bali, where the future is thought of as already in a sense past and determined, chronological sequence becomes virtually meaningless, and people date a finished work by the week and month, but omit the year. Studies of life histories are a revealing method of counterpoising an individual's idiomatic version of his culture against another type of description of its regularities, but the form that his idiom will take, the type of details which he will select, the sorts of omissions which he will make, will be found to be culturally regular, in spite of the deviant circumstances of his life, and the strength and originality of his temperament. Dreams and visions have been continually demonstrated to be limited to very narrow confines by the culture, and when memory experiments are made, individuals from different cultures, presented with a foreign tale, in recall give it a cultural as well as an idiosyncratic stamp.

All formulations which seek to class phenomena, or facts, as "cultural," "psychological," "individual," "idiosyncratic," "somatic," fail to recognize that all of these categories are categories of observations, points of view taken by science, and that all phenomena of human behavior may be looked at from each of these points of view. There are no "cultural facts"; there are merely orders of data which those who are interested in studying the cultural aspects of behavior, have found it most convenient to analyze. An individual's behavior in a memory experiment, or a multiple-choice reaction time experiment, or a test in which a psychogalvanometer is used, is culturally patterned,

but such material may not be the most appropriate for cultural analysis.

It will be useful for students of personality to recognize which types of cultural study provide them with which types of material. In the two branches of the "functional school," represented by Radcliffe Brown and Malinowski, individual differences between human beings were purposely held rather constant, and the emphasis is upon the way in which societies vary in their institutional arrangements for satisfying the same needs—hunger, love, social solidarity, etc. Structural differences in institutions, and differences in the way in which they function are studied so as to throw light upon the nature of human institutions, their possible range, the type of population for which different institutions are most appropriate, etc., and to arrive at methods of classification which will apply to all known cultures. These materials yield extraordinarily little that is immediately relevant to the student of personality, except as a by-product of rich detailed field material, or brilliant descriptive writing. Systematically, even the differences between cultures are only significant as a method of arriving at a statement of similarities at a higher level of abstraction. Only the beginning student of personality who still needs, for instance, to get a picture of the very different forms which the human family can take and the different ways in which it can function, will find this approach relevant.

The historical approach to culture which developed in America under Boas emphasized both the distinctiveness of each culture, and the dependance of each culture upon the availability of different sorts of cultural invention and upon historical circumstances such as migration, contact, etc. The common heritage of human beings was again heavily emphasized, and the "culture area" concept which described the regularities inherent in a group of cultures carried by people who had been historically in contact with each other, was a systematic way of referring the behavior of members of each culture to a wider base. This culture area approach may be used in certain types of discussion of personality as when we say that shame as a sanction governing behavior is characteristic of the North American Indian, although its use may vary from a complete dependance upon being found out and ridiculed, through a culturally cultivated ability to be insulted all alone in the middle of

a lake by the failure of a paddle to yield to one's skill. Discussions which find it useful to recognize certain historically and geographically relevant emphases which are wider than single tribes or native states, as when we wish to use the term "European" in discussing land tenure, or "Continental American" in discussing for instance, the way in which the mother's role in the child's life has been maximized at the expense of the father's in both North and South America, find this culture area approach valuable. The same basic methodology makes it possible to discuss "Catholic" aspects of personality development, or "Protestant" or "Buddhist" emphases, in which a traditional religious form which transcends boundaries carries with it some definite implications for personality development. The culture area approach may be seen as a systematic method of defining limits within which history may be assumed to be constant. It is assumed that all of the cultures in a given area have had access to all the themes characteristic of that area. This approach can be contrasted for instance, with an explanation which would ascribe those aspects of Rumanian character which the Rumanians share with other Rumanians, to a series of local events within Rumania. Under the culture area approach, the student would instead emphasize that these aspects of the Rumanian character were a stated version of "European character." This American historical school was not preoccupied with the study of "cultural character" or individual differences, so that its contributions to the study of personality, are either on this theoretical level, or in terms of a wealth of rich, verbatim materials which require considerable background to interpret.

During the last twenty-five years there has been a strong emphasis in anthropological study and in the related fields of social psychology, sociology, psychiatry, and psychoanalysis, upon the importance of what has been called, not very happily, the culture and personality approach. The *and* originally introduced to link fields, has proven to be a methodological embarrassment. The recent psychosomatic movement when interpreted at its broadest is a further, more systematic phrasing of the essential unity of the individual *in* a culture and the need for insisting upon a recognition of this unity, while his behavior is studied from a variety of points of view.

The earliest efforts in this field involved using cultural data, and making actual field investigations, to call in question theories developed within our own culture by students of personality such as G. Stanley Hall, Freud, Piaget, etc. The data on personality in other cultures were examined and arranged to show that human beings were more flexible, less rigidly channeled in given directions, than the theorists who had not had the benefit of comparative cultural study had imagined. This method of subjecting any psychological theory to the test of cross cultural applicability has become a routine test of all theories of personality development. Yale University has developed a "cross cultural survey" in which assumptions can be tested against classified data on many aspects of many cultures. In those cases where the material is adequate—which unfortunately are not many—it is possible to test out an assumption as to whether a certain type of child care—i.e., swaddling to a cradle board—is regularly found with certain types of stoicism under torture, etc. While the emphasis in the use of comparative cultural materials has for the most part shifted away from this function of merely calling in question or reaffirming some current theory, this use also survives as in the arrangement of data from a different culture to illustrate rather than test a theory, as has been done by several members of the Yale School with the Stimulant-Response Learning Theory, and by Rohcim whose interpretation of Freudian principles was enriched rather than altered by his extensive primitive researches. Where the investigator uses a theory which has been developed in one culture as a tool to investigate another culture, but holds himself hopefully ready to let the new material modify the hypothesis, theory can be very useful, but where the student of personality is asked to take the trouble to master the details of an alien society merely to reaffirm some theory which can be studied more economically within our own, the effort is doubtfully rewarding. A curious backwash of the earlier use of cultural material to call in question some of the culturally-limited assumptions of Freud, has occurred in the application of the term "cultural school," to the approach of Karen Horney, whose work actually makes no systematic allowance for culture but does question parts of Freudian theory.

Meanwhile comparative students have developed more positive approaches to theories of

personality, using cultural explorations to broaden the basis of theory, add facets which would not have occurred easily to students of personality who operated only within our own society, and raise the level of abstraction in which theories are couched. Examples of such broadening are the addition of an emphasis on skin and extremities, to a theory of personality which laid great stress on the body orifices alone as the basis of personality formation, of the inclusion in a theory of learning in which goal oriented behavior is one of its necessary conditions of the possibility of behavior which could not be said to be goal-oriented in the same way, or adding to theories of personality which assume a necessary expression of personality conflict in parties, factions, etc., detailed studies of those societies in which none of these phenomena occur. Instead of Malinowski's classic demonstration that the attitudes which middle class Vienna reserved for the father, could be split—in the Trobriands—between a loving father and a stern mother's brother, we now have statements of the "Oedipus" situation which state broadly the great importance of the child's relationship to adult figures of each sex, without specifying the number or exact family relationship of these figures.

The approach developed by Benedict treats a culture over time as analogous to a personality over time, in which the basis of selection of certain types of behavior and the rejection of others can be much more consistent and highly integrated than in the life history of a single individual. The impetus given culture towards the development of such a pattern, which is delineated not so much in the interpersonal relations of individuals as in formal elements in the culture, religion, myths, formal speeches, magic, is regarded as a combination of historical accident and the selection and reinforcement of certain human potentialities at the expense of others. These potentialities are themselves derived from a study of comparative cultures plus a generous allowance for the occurrence of other unknown potentialities as exotic as those which have been recorded. In this respect Benedict's work resembled Malinowski's. He derived his human needs from a study of cultures, not from a study of biology, and then proceeded to describe the similarities in the institutions through which all cultures meet these needs. Benedict derives her sense of man's potential range from

the various cultural expressions which are available for study and then concentrates on the differences between cultures which have specialized in one or other of these potentialities. Her material is then presented as data on range of potentialities and as illustrative of the uniqueness of each cultural version of those potentialities. Benedict's theory may be regarded as the most culturally based theory of personality, as it does not rely upon any assumption of systematic differences in temperament or constitution, nor upon any theory of limited possibilities. My study of Sex and Temperament, Bateson's Naven, and Bateson's theory of deutero-learning which assumes a limited number of types of learning which may be differently combined and elaborated in different cultures, Gorer and Erikson's use of the body image as a basis upon which personality is built, all assume a systematically limited set of the particular potentialities of mankind which have been developed by a given culture. The use of Benedict's method cross culturally leads to further data upon the process of historical development of cultural uniqueness, while these other approaches lead towards a development of a theory of personality development in which the approaches of other sciences are invoked as well as the cultural. Kardiner's approach involves the acceptance of historical accident as necessary to his argument, as in his handling of the high male ratio in the Marquessas as an effective cause rather than as a condition under which certain types of personality development takes place.

Studies of ego formation, in which attention is directed to the sanctions and surrogates which different cultures use in developing individuals who will function satisfactorily within their special limits, bring out rather sharply the present state of our knowledge. We have accounts of character formation in which the primary sanctions invoked are fear, anger, dependence upon love and authority (guilt), and shame (introjected standards of a group which is not wholly respected) and honor (introjected standards of others' respect for self), but we have no way of knowing whether this exhausts the possible categories of ego organization, nor whether our present continuum between degrees of internalization or externalization of standards is the only relevant one.

Students of the cultural dimension of personality can work from several quite different

angles and arrive at internally consistent results because of the complexity and internal consistency of the material with which they deal. The concept of culture rests upon the finding that items of behavior of many different orders, a gesture, a relationship between parent and child, a method of addressing the deity, a convention for the composition of poetry and a system of mortgaging property may all be seen as systematic. As an analysis of any series of these details—as the whole range of inter-personal relations, the art forms, the religious beliefs, or the methods of commercial behavior, is designed primarily to be a way of studying the whole, of defining either the whole culture or the culturally regular character of a carrier of that culture, a valid analysis of any one series makes it possible to derive the whole from it. So it is that approaching a study of a culture from the standpoint of the body and outlining the ways in which different parts of the body, particularly orifices and limbs and eyes, are treated in the developing child, if carefully pursued will produce the same type of generalization as may be obtained from a study of developmental history of children or from an analysis of the pattern of inter-personal relations such as Bateson's use of the place of parents and children in a series of paired relationships such as spectatorship-exhibitionism, dominance-submission, suckling-dependence. Bateson was able to show that many of the conspicuous and regular differences between English and American social practice may be referred to a reversal in the parent-child position, as in England the father is the actor, the child the spectator, in America the child acts and the parents are spectators. Benedict's type of analysis in which a series of variations on a wider spread theme, such as different European attitudes towards inheritance, wife's handling money, meaning of adolescence, interpretation of the historical events of the 1840s, etc., may be analyzed to give a picture of the personality of a given European society, also cross checks with these other approaches. Students who are accustomed to think more about the validity of a given method than about the wholeness of the phenomena which they are studying are sometimes puzzled as to *which* is the valid approach to the cultural dimension of personality. Actually the question is neither one of validity nor reliability but rather of availability and accessibility

of different types of data, and the temperamental or theoretical slant of individual workers. All the disputation as to the relative advantages of one approach or another is rooted in methodological arguments which are actually extraneous to the issue, the accurate delineation of the culture in such a form that cross cultural comparisons can be made, cross cultural abstractions constructed, and our frame of reference for the understanding of personality widened. The most recent work in psychosomatic medicine in which a diseased condition can be referred to the character structure of the individual, which can in turn be referred to his culture, provides a sort of synthesis of all of these approaches. A shifting disease incidence, as in the shift recorded by Mittelman and Wolff from women to men in incidence of gastric ulcer, can be taken as data on historical change, or in turn data on historical change may be used to reinforce the understanding of the cultural and idiosyncratic dimensions of gastric ulcer.

All of these modern approaches have in common the acceptance of a common humanity in which the characteristics upon which racial classifications are based are relevant but which recognizes a wide range of individual differences and temperamental potentialities. Whether this range is regarded as embracing a certain number of constitutional types or a limited number of possible directions of variation, or whether no such limitation is included in the hypothesis, all work in this field emphasizes the development of personality within culture, individual organisms interacting with other individuals whose behavior has been formed in the same process, under the same set of institutions. Types of behavior which we customarily regard as generically human, which include the use of language and the use of tools, already of course, involve a cultural dimension. We would not accord full humanity to an individual who had been reared without the intermediation of other human beings whose behavior was already culturally patterned.

In addition to the conceptual differences in approach to the problem there are a series of different methods of studying personality in culture, three of which are of special interest to psychologists: (1) the life history approach, (2) the observational cross section approach, and (3) the use of projective tests. It is impor-

tant to emphasize that while it is possible to reach the same generalizations by the use of any one of the *approaches* discussed above, because all of them are rooted in an orientation to the whole culture, the same thing cannot be said of all *specific methods*. Methods which have been developed in psychological research and are focussed upon non-holistic aims, but rather upon the need for a measure that is valid and reliable, cannot be relied upon to present a sufficiently representative sample of a culture so that the whole can be constructed from the part which is revealed by the test. This is essentially because most of these methods, with the exception of projective methods, are not a way of eliciting the pattern in the material but rather of forcing pattern upon the material. The patterns enforced are a product of our own society in its particular manifestation of scientific thinking, and may do excessive violence to the culture in which they are used. For example the life history method, in which a single individual or a number of individuals relate their autobiographies, involves an attitude towards sequence and chronology which is absent from many cultures and also necessitates an allowance for retrospective falsification, suppression, distortion and displacement, which can only be made completely if there are other cultural data from which the nature of these processes in the particular culture can be derived. Cross sectional observational studies, while less formal and so doing less violence to the material, nevertheless when formalized may introduce units which are irrelevant, either in the age sections chosen for observation or the units of behavior into which the observation is arbitrarily forced. Tests of a more formal nature, such as tests of intelligence, personality inventories, etc., are obviously so much a function of our own culture as to be generally unsuitable for cross cultural use. The Stewart ring puzzle test, a three-dimensional manual maze test with graduated levels of difficulty, comes close to being a cross-cultural test of intelligence precisely because it involves so much of the whole personality; persistence and concentration, degree of goal orientation, etc., being involved as well as visual, manual and kinaesthetic manipulation.

Projective techniques involve a hypothesis about the whole personality which is completely congruent with a cultural approach. Most of

the tests which have been devised to discriminate between types of personality in our own culture can be used as cross cultural tests of cultural character, once adequate culturally relevant standardization has been developed. In a test like the Rorschach, the present method of scoring and interpretation is designed to hold both temperament and culture constant and concentrate upon the developmentally-idiosyncratic pattern of the individual and so is not highly adapted to cross cultural use. The Goode-nough test, the "Draw a Man and a Woman Test," the use of family dolls, etc., all serve to demonstrate cultural dimensions to those who are familiar with the tests but unfamiliar with cultural thinking, and provide a convenient form for comparative work between our own culture where such methods are widely used to discriminate *individual* differences, and other cultures. To date, it has not been demonstrated that they reveal any aspect of culture which cannot be arrived at by other means, which is a claim which can be made for projective tests (as a type of test) in the study of personality within our own culture. Their use in cross cultural studies is primarily justified by a need to communicate with workers in other fields of personality study.

Another question which is frequently raised is the role of experiment in cultural studies. In the first place, cultural study is at the present time a clinical science. The aim of training is to develop an individual who is sufficiently well versed in the perception of pattern in the phenomena of human behavior so that he or she will be able to delineate the pattern of a given culture. While there is continual pressure to develop cross cultural abstractions which will bring more phenomena within a single frame of reference, there is as yet no hope of producing abstractions which can be arrived at by any foolproof means, such as a test which can be administered by an experimenter ignorant of the theory on which it is based. Although increasing techniques for the collection of kinship systems, for instance, have made it possible for less gifted research workers to bring back fuller material, these improvements have not kept pace with the constantly accelerated demand for greater theoretical sophistication which must be included in the observations when they are made. Attempts to use still and moving-picture photography to standardize observations have

only revealed the importance of the observer's point of view, which is as significant an element in anthropological field research as is the "transference" phenomenon in psychoanalytic investigations.

So it is necessary to distinguish between the "cultural" approach, recently very well described by Kurt Wolff, and the "objective" approach which has been the aim of much of psychology and some anthropology. In the first approach, the investigator is included within the observation; any observation is regarded as a product of the culture of investigator and culture of the individuals being observed. By comparative means and the accumulations of observations made from different cultural approaches it is hoped in time to establish a science which will be comparably usable in different cultures. But this approach does not hope to arrive at scientifically valid results by *excluding* the investigator nor by holding the investigator constant.

The study of culture is primarily an observational science which relies upon the necessary conditions having already been created by history. Students take the trouble to journey to a strange society, learn the language, and study the culture in detail in order to benefit from the natural situations which occur there because cultures have been historically differentiated. Experiments tend to force our frame of reference upon the individuals in these other cultures, even more drastically than do tests, just as maze experiments force our theories of learning on the rat. There is an essential contradiction between the experiment which relies upon the competency with which the experimenter imposes his conditions and the method of observation in which the observer finds his answer the more completely he leaves the conditions unaltered. While a certain number of experimental methods, such as memory experiments, may be necessary for purposes of cross disciplinary communication, there seems no reason to believe that experiment is a very fruitful way of studying the cultural dimension. In occasional instances as where knowledge of a culture is lacking, and action in that culture is imperative, as in the problem presented by the need for planning for the reeducation of German youth in 1945, experimental set-ups which parallel situations in other cultures where more of the relevant factors are controlled may be short-cuts to action plans. But this is due to the

need to apply knowledge before knowledge has been obtained by better means, not to the greater suitability of the method.

Method in this field is primarily oriented towards a recognition of the systematic nature of human behavior, towards a recognition of the inter-relatedness and integration of all of the details of a culture, rather than to specific techniques of analysis. In this respect the general cultural approach stands to the methods of psychological testing very much as the general clinical approach stands to the specific diagnostic techniques of the laboratory. Conceivably as psychology takes more systematic account of the cultural dimension, specific, finely calibrated tests may be developed which the anthropologist can use with the same reliance as a clinician places upon urinalysis, blood analysis, etc. But even so, both clinician and anthropologist have to refer the sets of specific findings to another frame of reference, the total personality for the clinician, the culture for the anthropologist.

So far we have been discussing the cultural dimension as it applies to the regularities of personality within a given culture. We may now turn and examine in more detail the various patterns of difference between personalities within a culture, which can be referred to the culture.

One of the most important forms of such differentiation has been discussed by Linton under the heading of status. Some status attributes are regarded as virtually inalienable aspects of personality, such as sex and age, rank and caste, lineage, date of birth, place of birth, order of birth, nature of birth (e.g., child born in a caul), legal status of birth, etc. There is no one of these, some of which we regard as inalienable and significant and others of which we ignore, which some human culture has not regarded as less significant, or reversed the "natural connotation," even of age and sex. In Bali the sounds made by infants are invested with the dignity of supernatural revelations; in some societies the very old are reduced to child stature. Complete sociological change of sex, including transvesticism, change of occupation and removal of all barriers to acting as a member of the opposite sex, occurs in many societies.

However, whichever types of recognition a culture accords become important conditions of personality differentiation. Whether children are supposed to be quiet and mouselike, or

noisy and troublesome the quiet fearful child and the active aggressive one have different fates and respond differently to demands congenial to one and uncongenial to the other. Whether women are supposed to be meek, responsive and clinging, or bold and initiating, the variably successful attempts of different women to approximate the cultural expectation is an important factor in personality formation. The society which believes witchcraft is hereditary in the female line singles out the girl children of alleged witches and treats them so differently from others that the girl almost inevitably develops a personality to which witchcraft may plausibly be attributed. Princes and nobles, given special treatment from birth, surrounded by servants and subjects, develop very differently from commoners. The child without a name may hang its head in shame or carry it too high, but because its culture has decreed a difference between those born in wedlock and those born outside, it will never carry its head just as it would have if no such distinction existed. The seventh child of the seventh child is oriented towards clairvoyance differently from its brothers and sisters. So it may be said that every structural complication of status which a culture includes, which carries an attributed difference in personality or an attributed expectation of or right to different behavior, will contribute to the diversification of personality within that society. Depending upon the type and strength of the cultural pressures, such structural definition may actually produce different personality types in nobles and peasants, each systematically related to the whole culture but differing consistently as between the two groups, or the stylization may merely result in the aristocracy rejecting its own members who show "peasant type" behavior, and giving every opportunity to any member of the lower group who shows himself of "noble mien" to rise. But whatever type of resolution between assumed personality ascribed to a status with which there is no necessary connection happens to occur, the range and type of personality difference within the society will be a function of such cultural distinctions.

It is also useful to discriminate the cultural patterning of personality differences by the emphasis laid upon such situations as being an only child, the child wife of an old man, which may be culturally usual in one culture, treated

as exceptional in a second, and ignored in a third.

Kinship may be patterned so as to give the same individual a chance to play a variety of roles and so express a greater number of facets of personality without, however, increasing the degree of differentiation as between individuals in a society. In such societies as the Bathonga of South Africa, many primitive Australian tribes, and the Crow and Omaha Indians, for instance, a man treats certain relatives with respect, others with familiarity, others authoritatively, others perhaps with avoidance. This often means, as in Bathonga, that every person has a chance as an adult to live out different sets of inter-personal relationships, to treat his own child sternly and a sister's child indulgently, for instance, yet because these roles are enjoined upon everyone their diversity may actually tend to reduce personality differences as among individual members of the society. Greater authoritarianism or greater tendency towards giving or receiving indulgence will be masked by the large amount of institutionalized outlets permitted. In a very simple society such as the Temiar of Malaya, the difference between the shaman and the rest of the group may on the other hand constitute an enormous difference in personality, a different order of personality integration being required of those who achieve shamanship. At every turn it is important to ask both what is the degree of differentiation, the number of similar roles permitted to every individual in terms of age, sex, occupation, kinship status, place in hierarchy during their lifetime, and also to what extent are these structural details patterned to differentiate among individuals. Where kinship is very important, the circumstance of being an orphan, the last of the line, the single member of a clan, doubly adopted, etc., may serve to place the individual in a position where others behave to him with, and expect from him, very different responses, as he is expected to be lonely, misanthropic, independent, lacking in independence, etc., according to the cultural emphases. It also makes a great difference whether a society permits contrasting types of behavior, such as sexual license, drunkenness, in those who are ordinarily circumspect, at a given period in life, at a given period in the year, or only to those who are on the point of leaving for battle, being

offered up to the gods, or who belong to certain religious societies. In the first case, everyone who lives through a normal life span will have both sets of experience, control and license, and everyone's personality will reflect systematically the alternation. In the second, the license given to some and withheld from others will have a different sort of reflection in personality differences.

Perhaps this contrast is brought out most strongly if one compares two mechanisms, that of different treatment of children because of their present position in the family (youngest, knee baby, third from the last born, etc.), and because of order of birth. When children receive several types of treatment in sequence, there is a complication of each personality structure, as the developing child experiences each step in the sequence. It seems possible to refer some of the puzzling differences between cultures as to the depth and variety of their symbolic systems to the extent of this sequential variation by which a child may be first pampered, then ignored and then given responsibility for the new baby, before it becomes a member of a large, relatively homogeneous "children's group." But each child in turn, even the youngest in a single family, receives this sequentially differentiated treatment from all the members of the society. The end result is a richer culture, a richer cultural character or basic personality structure, but not necessarily any greater differentiation among individuals. Although as a general rule, the more complexity a culture has, the more possibilities for the diversified realization of personality exist, the masking effect referred to above may obscure temperamental differences which would be more sharply accentuated in a culture in which men and women, or members of different classes are sharply distinguished in cultural usage. Order of birth differentiation, like sex, rank and caste differentiation, is of this latter type, and where strongly emphasized it may be possible to tell at once whether a given individual is an eldest or younger son, the son of a man of rank or position, or as is the case in Manus, there may be a combination of rank and situation so that it will be possible to distinguish among the sons of a man of rising importance and recognize which child was at the most formative stage when his father reached a peak of social importance. Or, instead

the differentiation may be between households, as in Samoa, or even between villages, and individual differences may be muted to the emphasis of an extended family or a whole hamlet.

In addition to recognizing these two extremes of cultural patterning of individual differences, where each individual is patterned in the same way, and where there is a highly culturally patterned degree of difference among individuals, it is important to recognize those areas in which there has been no cultural emphasis of any sort, which are perhaps the crucial instances for the study of certain "natural" or universally human, or constitutional differences. Cultures may be highly animistic, or insist on a high degree of objectivity—like our own, or there may be relatively little interest in whether individuals conceive the world in animistic and arbitrary, or mechanistic, cause and effect terms. In such cases difference in imagination and style of interpretation of casual events will be found, if the behavior of individuals is observed carefully. The same holds true of order of birth in a culture which is uninterested in the subject, which has no terminology for birth order, no privileges or duties or expectations according to order of birth. Just how much we may attribute the differences or similarities in animistic thinking, the differences between children of different birth order, etc., which are found in such cultures, to some universal or constitutional difference, and how much they must still be regarded as inarticulate but patterned reflections of other areas of the culture which are articulately patterned is a problem which awaits further study. A striking example is the occurrence of marked phonetic differences in pronunciation between individuals who live on the border of a phonetic shift within a common language, such as so often occurs in Oceania, where one group may use a *k* and another a glottal stop, or one an *r* and another an *l*. If the border line is vague, there will be found a consistent variation between individuals, some always using the *r*, the others the *l*, where the culture permits either. This may reflect a true temperamental difference, or be a hidden but still patterned form, of some characterological phenomenon like resistance or acceptance of parental authority.

Finally, one of the great unanswered questions of the problem of personality in culture is

the extent to which it is possible to assume any system of drives, internal impulses, or physiological functions, which remain relatively unpatterned by the whole cultural process, but are simply differentially converted, displaced, sublimated, satisfied, etc. There is some evidence to suggest that there is a level of personality, which reappears in extreme schizophrenia, which may be remarkably unpatterned. Some drawings of schizophrenics partake of the nature of the drawings of schizophrenics in other cultures, rather than of the nature of drawings by sane members of their own culture. On the other hand, drawings by paranoid schizophrenics in the United States in the Abel (Free Designs of Limited Scope as a Personality Index) test and drawings by socially functioning Balinese artists are indistinguishable, while the drawings of other exotic peoples on the same test reflect cultural superstructure rather than what appears to be here, a more basic organization of personality. The extent to which the "primary process" in Freud's terminology, is actually culturally patterned has never been adequately investigated because the investigators have taken too heavy a theoretical paraphernalia to the interpretation of the phenomena of other cultures. Psychoanalytic phrasings of the nature of drive expression and stimulus-response phrasing of the nature of learning, and the human needs phrasing as the basis of all institutional superstructures, all provide workable descriptions of other cultures and of the process of personality formation within them, but none of them permits a sufficient amount of theoretical freedom for the student of personality to learn more about theoretical possibilities from the concrete data of each culture studied.

PERSONALITY, MEASUREMENT

OF.—Personality, used as describing certain factors in the total individual, may be interpreted in various ways, depending on the point of view. Objectively, we can say that it is that which we do in relationship to other people. We may also take the position that it is that and more, that it involves the motives which influence our actions and our character. Or we may say that it consists of the effect of a combination of inward personal experience and outward social behavior. As Dashiell¹ puts it, an individual's personality is, "a sum total of behavior trends manifested in his social adjust-

ments." Psychiatric interest in the individual began approximately 160 years ago in France when Pinel humanized the care of the insane. Along with this interest came a concern for classifying, if possible, the mental disorders. This gave him an opportunity to recognize individual variations among the institution inmates. Griesinger and Kraepelin following Pinel, sought to refine and delimit his work. Both were much interested in observable effects. This type of approach to the problem was used until close to the end of the nineteenth century when the psychoanalytical point of view, with its major emphasis on early developmental influences and dynamic relationships began to make its influence felt in the field of psychology. Bleuler and Adolph Meyer bridged the gap between this early method and that of the Freudian group.

The contributions of Freud and his associates, Jung and Adler and Levy, to the area of personality cannot be underrated. They may be said to have fathered the practice of personality testing. To Freud we are indebted for the work in breaking the personality into the *id*, the *ego*, and the *superego*, and the theory of the building of personality by the interplay of these three factors. Jung's contribution of the doctrine of complexes, Adler's theory of "individual psychology," and the work of Levy in the guidance approach to the study of personality laid the groundwork for the next step, measurement of the personality.

As a result of the introduction of psychoanalysis there was a direct interest created in the study of the earlier years of the child and their influence on later behavior and personality development. This helped to give the present child guidance movement individuality. The growth of the mental testing movement in psychology dovetailed into the interest of the psychiatrist in individual variations. The psychologist now stepped in with a measuring device which was especially applicable to children by which their intelligence could be weighed precisely and objectively. Next the psychologist produced a means of measurement of the individual aptitudes and capabilities especially in the fields of education and vocations. This definitely enlarged the scope of the child's total personality.

The story of the child's environment is im-

¹ Dashiell, J. F., *Fundamentals of Objective Psychology*, p. 551, Houghton Mifflin Company, 1928.

portant in understanding the development of the behavior and the personality of the child and the later adult. It also gives direction in the treating of undesirable deviations. Research in this area has not been extensive nor has it yielded an abundant harvest. Nevertheless reliable personality tests have been constructed. The most serious impediment to the whole personality trait testing program is the apparent inability to find a sure method of determining *validity*. Since validity not only presupposes that a test measure that for which it was constructed but also the significance of the trait which is measured as well, the problem presented still calls for considerable research. The cause of the difficulty in this area lies in the fact that although people differ one from the other in personality, the differences are not sharp and clear and the traits are not capable of placement in categories by which the tests might be validated. Diligent search has, as yet, produced little in the way of sifting out and classifying individuals by their personality traits. When the validity of a test is questionable, then any interpretation which might be made of the results of the test would necessarily be questionable. Until there is some definite means of obtaining tests of high validity any use of personality test results must be made with considerable care. Used in conjunction with achievement tests in the field of guidance, they serve an invaluable purpose in supplementing and reinforcing the results of those tests. Some attempts have been made to validate personality tests by correlation with a judgment criterion. Since judgments of abilities are subject to considerable errors, any validation of a test by this means is open to question. Many statistical psychologists take the position that if a test measures a trait reliably then the measurement of the trait is valid. This calls for the inclusion in the test of only those items which contribute to the total score. The next step then "involves determination of the maximum validity possible . . . afforded by a statistical or mathematical validation and not by correlation with an outside criterion."²

Another method used in an attempt to validate personality tests is to correlate the tests with outside criteria, of course with full knowl-

edge of the errors involved. Correlation coefficients obtained in this manner are obviously low, probably averaging between .40 and .50. Until some definite method is evolved for obtaining greater validity, interpretations of the scores of personality tests must be accepted with caution. The interpretation, then, can be only indicative of possible behavior and not prognostic.

The various ways by which attempts to segregate and identify personality traits in individuals by personality tests may be classified under three headings, rating scales, questionnaires, and inventories.

RATING SCALES

In this area there are two divisions, (1) rating by trained observers or raters, and (2) self rating. In locating personality traits by two or more observers or raters, certain precautions are generally taken to make the rating as valid as possible. Raters are cautioned against committing the "generosity error" by giving their acquaintances the benefit of any doubtful judgment and against the "halo effect." Raters should of course be free of bias, and be well enough acquainted with the individual rated so that their ratings are more than a mere guess. Pooling or combining ratings of various observers is generally accomplished by each rater turning over his rating sheet to a computer or the raters meet and compare notes and as a group attempt to agree on a rating for the individual. It is obvious that the validity of any such personality rating is very low, although reliability may go as high as .80.

Self ratings probably have a tendency to be rather higher than observer ratings due to the human desire to appear better than the average of society. Among the self-rating scales validity is not conceded even by the makers to be very significant.

QUESTIONNAIRES

A questionnaire in general is a list of questions which the individual is expected to answer by checking or writing "yes" or "no." From the viewpoint of Psychology this method is designed to have the individual reveal by his checking where he stands along a given dimension of his personality. Some of these questionnaires, particularly the "trouble questionnaires"

² Patterson, D. G., Schneidler, G. G., and Williamson, E. G., *Student Guidance Techniques*, p. 171, McGraw-Hill Company, Inc., 1938.

reveal a rather high degree of reliability. Validity, however, depends considerably on the use to which the scores are to be put. If its purpose is to discover neurotic possibilities, its validity can only be determined by waiting over a long period of time until those who showed neurotic tendencies develop personal difficulties from which those without the tendencies remain free. This method, however, has many exceptions.

In tests to determine emotional stability in an individual, it is possible to have errors entering into the checking by those who have been coached up on the type of answers expected. In the study of individual differences the trouble questionnaire may be of use. It may receive some validity in this area by subsequent interviews with the individuals who checked it. Even then the validity of the questionnaire is low.

Questionnaires have been prepared in great numbers for many other traits, to aid in correct vocational choice and for revealing the trends of the many interests of an individual. They are also prepared to measure attitudes on many questions such as, economics, religion, politics, etc. Fortune and Gallup polls are of the more widely known types of the questionnaires. The Bell Adjustment Inventory and the Johnson Personal History Record are of the questionnaire type.

INVENTORIES

This kind of testing covers a wide range of traits varying from the performance tests, personality inventories and the imaginative responses of the Rorschach type. Performance tests seek to discover the individual's interpretation of character traits which are the basis of personality, such as honesty, generosity, persistence, etc. Personality inventories attempt to measure traits of personality adjustment. They may be of the questionnaire type as the Bernreuter Personality Inventory which purports to measure six traits. They are generally of use as indicators of symptoms of maladjustment. As yet personality inventories are still in the experimental state.

In the Rorschach Technique, using the imagination in conjunction with the inkblots, it is claimed that the individual reveals indications of his interests, preferences and emotional trends as well as his abilities and experiences. If it were possible to induce the individual to

free his imagination completely and talk freely at the same time, he might reveal his personality in this test. It is similar to day dreaming. In order to obtain anything more than a weak impression of the individual's mind from this test it is necessary to compare the responses of many persons. In the Rorschach method this has been done and a system of scoring has been worked out. The validity of this test may be checked by analyzing the individual's personality by some other means and comparing with the Rorschach results. Although in some instances the check has come out in favor of the method, there is still much more to be done before it can be used as more than a means of indication of the probable traits of the individual's personality.

The lack of validity which is a grave fault of personality tests does not necessarily prevent their use. They can be of great value to the individual tested and to the examiner as a means of obtaining insight into mental characteristics which are otherwise overlooked. The proposing of the questions tends to focus the individual's attention and thinking on those areas which are in need of remedial treatment. Such personality features as defects of character, annoying mannerisms, and inefficient actions may be revealed by these tests for the first time. To this extent the existence of the tests is justified.

Much work needs to be done in the testing of personality traits before they can be called adequate measures of personality.

PERSONALITY DEVELOPMENT, THE ROLE OF THE FAMILY IN.

I. THE BIOLOGICAL ROLE

What the family contributes to human personality¹ is difficult to state because the family's contribution to personality is both indirect and direct; that is, biological as well as social. The family gives an individual his hereditary qualities and even if he loses his parents at birth and is reared by others, his personality is in some ways influenced by the peculiar endowment he received from his forbears. This biological contribution of the family to personality is largely indirect (although the hereditary endowment is handed down directly from parents to offspring), because the hereditary factors do not by themselves give us our personality traits. These depend directly on our experiences, and particularly those of the early years of life centering in the family.

The family's biological contribution to personality can be touched on only briefly in this article. The contribution is instantaneous and final, for once the egg has been fertilized, it contains all the hereditary factors it ever will have, even though in some cases it may take years for the structures to mature, as in the case of sex. The fertilized egg contains 48 chromosomes, half of which are received from each parent. The child obtains his biological inheritance from his parents, but they obtained theirs from their parents, and so on back. The child is therefore indebted not alone to his parents but to all his ancestors for his particular inheritance. In any individual case it is not possible to estimate exactly how much of a child's inheritance can be attributed to his immediate family, but on the average Galton's "Law of ancestral inheritance" has been found to hold. The child's parents contribute between them one-half of each inherited trait, the four grandparents supply all together one-quarter of each characteristic, the eight great grandparents one-eighth, and so on, the various fractions—one-half plus one-fourth plus one-sixteenth—finally totalling one, or the sum of the child's inheritance.²

Biological versus social heredity. The initial cell or fertilized egg is multiplied countless times by division and subdivision, producing ultimately the completely developed individual. As the cells multiply, they become specialized

as to function, such as the building of muscle, bone or skin. But some of the cells remain segregated, namely the germ cells which are later available to continue the life cycle. These germ cells are replicas of the parent germ cells and remain unaffected by the ordinary experience of the individual and by changes in his body cells. It is for this reason that a man who loses his arm or leg in an accident may nevertheless become the father of a fully-limbed child. Similarly, if impairments of the body during lifetime are not transmitted through the germ plasm, drunkenness in the parents cannot possibly affect the child's heredity, although it may affect his development in embryo if the drinking is done by the mother to the point where it affects her health or nutrition. And, of course, the environment of heavy drinking will not be without its effect on the child after he is born. But the point to be stressed here is that the germ cells, or carriers of heredity, are isolated from the rest, which is nature's way of preserving them from harm. If impairments of the body during lifetime are not directly transmissible via heredity, neither are improvements in the parents in body or mind, due to good diet, proper exercise or learning. The parents may both be Ph.D.'s but the mental endowment which their children receive from their heredity would be exactly the same if neither parent had had a single day of schooling. However, the children would of course benefit after birth through association with their highly educated parents. The inviolability of the germ plasm means that the advantage gained by one generation through education and learning must be transmitted to the next generation via the learning process if it is to be retained. There is no gain in literacy, in morality, or in any other virtue which must not be won anew in every generation through education. This point is highly important, for it shows that there are two mechanisms of transmission, the one biological via the germ plasm, the other social via learning. These processes are very different, even if related, and much harm can result from the failure to distinguish between them.

A corollary of the point just made is that we inherit structures of various kinds but not functions. When we say that the genes are the determiners of heredity we mean they determine the structures. For instance, the apparatus of speech is inherited, the voice box, the pharynx,

culture. In the United States we have no homogeneous culture and no single pattern of parent-child relationship is as conspicuous as it is, say, among the Manus people, although there is a fairly general feeling that mothers ought to look after their children, especially when they are little. Other patterns are permitted, however, in different groups, such as the assignment of children to governesses by the rich and placement of little children in day nurseries and nursery schools by working mothers. The culture, then, dictates more or less what the relationship of mother and child shall be, especially during the child's infancy. But the relationship between mother and child is not wholly determined by these traditional factors. Other factors, of a more personal and local character, also play their part in affecting the relationship. Such factors are, for instance, whether or not the child is planned for and wanted, whether the parents desire a boy or a girl, how much discomfort the pregnancy causes the mother, the health or sickness of the infant, and so on. These are considerations which are personal and which concern chiefly the individuals involved, hence may be referred to as group or social factors, in contradiction to the more general cultural factors. It may be argued by some that the considerations just mentioned are not personal but really cultural in origin; that for instance, the preference of parents for a male child in our society flows from the fact that in our culture males have more privileges than females, and it is perhaps easier to rear a boy than a girl. If the preference for male births is cultural, how then shall we account for expectant parents who hope greatly that their baby will be a girl? The answer may be found in the personal experience of the parents, but hardly in the prevailing culture patterns. So it is with much of our interaction with others. The type of relationship we develop depends in part on special, personal factors as well as on the more general, traditional pressures of the culture, although in practice it is exceedingly difficult to distinguish between the two.

Special importance of the early years. One of the great discoveries made by the psychoanalysts has to do with the special significance of the early years of life for personality. Previously it had been thought that not much of any consequence happened during the first five or six years. The very early experiences are

hard to recall, especially those of the first two or three years, from which it was assumed that the experiences could not be of much importance. The over-emphasis on heredity, which is not so great now as before but still great, obscured the importance of early experiences. For these reasons and others the average person glosses over his childhood experiences as if they counted for little, and if he is writing his autobiography, dwells largely on the achievements of adulthood. It is much nearer the truth to say that the earlier experiences are the more important for they set the direction in which the person is to go. As the twig is bent, so is the tree inclined. The early experiences are important because they come first and build up mental sets that condition all later learning.

How the very early influences leave their mark may be illustrated by the case of a college senior who despite notable achievements in many fields labored under a feeling of acute inferiority. He was editor of the college daily, president of his class, a member of the golf team, a leader in his fraternity, yet confided to friends that he felt he deserved none of these honors except the golf but they came to him only because others were mistaken in their judgment of him. If they really knew him, they would not choose him, and he felt that the revelation might come to them at any moment. "I'm really dumb" he would tell his close friends. Since there was nothing in his present situation to explain such an attitude, an inquiry was made into his past experiences and disclosed that when he was a little child he was discriminated against by his father, who preferred a more brilliant brother who was somewhat older. Very early he acquired the idea of inferiority, especially intellectual inferiority. This led him to develop along social and athletic lines, to the point where he had a remarkable facility for getting along with people and was a fair athlete. But the sense of inferiority that took root early in life was still with him, robbing him of genuine satisfaction in his achievements. This sense of inadequacy had been repressed because it was painful to contemplate, but it lingered in his subconscious and colored his estimate of himself.

When we say that the fundamental patterns of personality are laid down during the early years of life, we do not mean that nothing may later be done to modify these patterns, although

as a rule patterns once established tend to persist because it is easier to do nothing about them. The tenacity of these first patterns is very great, even when they are undesirable and do not help the individual to make satisfactory adjustments or produce happiness. Thus the persistence of self-seeking tendencies when laid down early is impressive. If a child, by virtue of real or imagined handicaps feels greatly inferior to other children and aggressively attempts to dominate others in school work, in play and in activities generally, he will in all probability grow up into an adult who seeks power over others. Sometimes the personality pattern is disguised but if one looks below the surface it can be seen to exist. At first the power-seeking impulses may lead a person to anti-social activities, as in crime. Later the person may be reformed. He is induced to give up criminal activities and take up pursuits that are approved by the group. He may become a detective and aid the forces of law and order. But it is important in these cases not to regard the change in social behavior as necessarily indicating a fundamental change in personality. The reformed criminal, now a detective, may be just as ambitious, just as self-seeking, just as anxious to establish himself over others, as he was before. The form of the drive has changed, not the drive itself. It is highly important for students of personality to distinguish between personality traits and social roles. It is possible, of course, to change some personality traits, although this is much more difficult.

Special role of family experience. If the early years of life are of special importance for personality development, it follows that the family occupies a commanding position in the field, since the child's earliest and most telling experiences are with his family.⁵ The child at birth is an exceedingly helpless individual, entirely at the mercy of others for protection, if not for survival. The small helpless child is protected by his family and from them usually gets a sense of security in life. This he gets through the furnishing of food and clothing and shelter by the parents, but even more by the parental expressions of affection and approval. Some psychiatrists, like Karen Horney, believe that the common denominator in neuroticism is a lack of genuine affection in early childhood.⁶ Criminologists likewise believe that the roots of delinquency are to be sought in the

emotional rejection of children by their parents. Healy and Bronner⁷ studied many pairs of twins, where only one of the pair was delinquent. Why, it was asked, did the one become delinquent and the other not? Analysis of the cases according to these investigators showed that in every instance the delinquent had suffered serious frustration in his family experience, whereas the non-delinquent brothers and sisters had not. These studies make out a strong case for the strategic role of early family experience in the formation of personality.

Ideas, especially moral ideas, play an important part in personality, and the influence of the family in developing such ideas in children is great, very much greater in fact than the influence of the school and the church combined. This observation is indicated by a report⁸ of the sources from which children derive their ethical concepts. A large number of children were tested as to their ideas of right and wrong, and the results correlated with the scores of the children's associates, as follows:

Child and his parents545
Child and his friends353
Child and his club leaders137
Child and his day-school teachers028
Child and his Sunday-school teachers	.002

The figures show that there is no agreement of any importance between the moral judgments of these children and those of their club leaders, school teachers or Sunday-school teachers, indicating that these persons did not influence the child's moral thinking in a positive way, at least insofar as the ideas tested were concerned. The connection between the ideas of right and wrong of the children and those of their chums is more significant but we have no way of telling whether the children got their ideas from their chums or selected out as chums those who happened to agree with them. In the case of parents, however, there can be no question of the casual relationships, since children do not choose their parents or parents their children. As would be expected, the mothers' concepts were more closely allied to the children's than were the fathers', reflecting the more intimate relationship usually enjoyed by the mother.

Divergent experiences of children in the same family. Although family experiences, especially those of the early years, are of primary impor-

needlework and culinary efforts were placed before women of the neighborhood, before friends and relatives, and highly praised. When her mother entertained her club, Nellie would join the women and sew and her handiwork would be passed around and admired. By the time Mary could toddle, Nellie was seven years old. Mary too tried to excel in baking and sewing. On bake day she was given a chance to make little cakes and she learned to make dresses for her dolls. Her work was as good as Nellie's had been at the same age, but naturally it suffered by comparison with Nellie's present handiwork. One day Mary brought out a little blue dress she had made for her doll and showed it to her maternal aunt, who examined it and observed: "Well, Mary, I am afraid you will never be able to sew like Nellie. You are like me. I could never learn to sew." Mary's father, noting her disappointment, tried to console her: "What if you can't sew and bake, you can be daddy's outdoor girl and help him. How would you like a horse to ride?" Mary put her doll aside and seldom played with it again. She followed her father about the farm and rebelled when her mother asked her to do housework. As her father had suggested, she took to riding and by the time she was 10, she took prizes for riding at the county fair. Each day she added some new accomplishment in the out-of-doors and became known as a tom-boy. She excelled her brother at target practice with a 22 rifle. Now she was daddy's outdoor girl, the champion shot of the Jones family, not just Nellie's younger sister.¹²

The only child. Brothers and sisters exert telling effects upon one another's personality which are different from the effects exerted by their parents. From both types of relationship, children gain perspective on themselves and training in social adjustment, but in dealing with their parents they learn response to authority, while in dealing with one another they learn to compete with equals. This puts us in position to see why, unless some rectifying influences are exerted, the only child develops certain handicaps of social and emotional adjustment. A number of studies show the greater difficulty of only children in achieving satisfactory adjustments in marriage, and there is supposed to be relatively more neurotism and unhappiness among such children. There is some evidence to suggest that they are more

often successful in the economic struggle than their numbers would warrant, probably because they have the advantage of better training, since they do not have to share the available family funds with brothers and sisters. However, the evidence on the position of the only child is not conclusive and a recent comprehensive review of the literature reports that in most traits only slight differences are indicated between children that have siblings and those that do not.¹³ It is possible therefore that the dangers of being an only child have been overdrawn. Perhaps the unusual popular stress laid on this problem has made parents more mindful of the dangers and has led them to take appropriate precautions. Also, the increase in the number of families with but a single child means that the situation is much less uncommon than it used to be, and that therefore only children are probably less sensitive about their status, which would be a favorable factor in adjustment.

M. F. NIMKOFF,
Bucknell University

NOTES

* This discussion is adapted from the writer's forthcoming *Marriage and the Family*, Houghton Mifflin, Boston.

¹ By personality we mean the pattern of a person's thoughts, feelings and actions, that is, his psychological behavior as distinguished from his physiological behavior, although many interconnections exist between these two fields. Habits, opinions and attitudes constitute the core of personality.

⁹ Case A, Chapter VII, Healy and Bronner, *op. cit.*, pp. 95-98.

¹⁰ Where partiality is shown, usually the parent is conscious of his behavior, but there are a surprising number of cases where the parent is unaware of his partiality. A mother of two daughters, age three and six, sought assistance in correcting undesirable behavior which the older daughter was showing. She was sullen, defiant, and uncooperative. When given a dress for her birthday, she cut it to bits with a pair of scissors. Investigation showed that the mother was slighting the older girl, who resented the discrimination and was resorting to unapproved behavior in order to get attention. When given this explanation, the mother strongly denied its validity and claimed she had equal affection for her two girls. However, it was pointed out that in addressing the older girl the mother simply called her by her given name but in speaking to the younger one the mother used terms of endearment, and the tone of voice was different. The mother also did many little things for the younger daughter which were not done for the older, like taking time to examine and praise things made or work done. When these differences were pointed out to the mother, she acknowledged them with some embarrassment as well as amazement that she had been showing partiality so plainly, yet unwittingly.

¹¹ Adapted from L. G. Brown, "The Development of Diverse Patterns of Behavior Among Children in the Same Family," *The Family*, 9, 35-39, April, 1928. For further treatment of this topic, see B. Weill, *Behavior of Young Children of the Same Family*, Cambridge, Harvard University Press, 1928.

¹² The above account is interesting in showing that, to gain distinction as a person, Mary had to develop interests different from those of her sister. There is another side of the picture which is not given, namely, the effect of Mary's popularity upon Nellie, which is also interesting to speculate upon.

¹³ W. Paul Carter, *The Only Child and Other Birth Orders*, doctoral dissertation, Chicago, University of Chicago Libraries, 1937. Studies in progress suggest that only children at Bucknell University do not differ significantly in emotional, social and health adjustment from a control group of non-only children. The groups were matched for age, sex, education of parents, occupation of parents, and I.Q.

PERSONNEL, TEACHER.—The research in this area has been dominated in the main by the immediate and practical problems of the field worker rather than by the fundamental issues and theoretical considerations of the scientist. Many different sorts of problems have come under investigation such as teacher supply and demand, the education of teachers, the measurement of teaching efficiency, recruitment,

selection, placement, teaching loads and assignments, salaries, tenure, pensions, certification and the status of teachers. Only a few of these many aspects of teacher personnel will be discussed here. The summary here presented will be limited to those aspects of the subject that seems most akin to subjects ordinarily considered by students of psychology, such as, the definition and measurement of teaching efficiency, factors conditioning efficiency, the education of teachers, and the prediction of teaching efficiency. For information relative to the professional and administrative aspects of this subject the reader is referred to the *Encyclopedia of Educational Research* by Monroe and others (21). The first subject to be discussed is that of the definition and measurement of teaching efficiency.

THE DEFINITION AND MEASUREMENT OF TEACHING EFFICIENCY

Definition of Teaching and Teaching Efficiency. The scope of the teacher's responsibilities have never been very clearly defined. In a sense every book, magazine or monograph that relates to teaching makes certain assumptions about the teacher's responsibilities and the prerequisites to teaching success. Nowhere, however, have these many definitions been collocated into a simple statement. One of the most comprehensive studies of practice was made some years ago by Charters and Waples (13). They attempted to define the scope of teaching by listing the activities performed by teachers in the discharge of their every day responsibilities. They listed the following major groups of activities: (1) activities involved in classroom instruction; (2) activities involved in school and classroom management; (3) activities involving supervision of pupils' extra-classroom activities; (4) activities involving relationships with the personnel of the school staff; (5) activities involving relations with members of school community; (6) activities concerned with professional and personal advancement; and (7) activities concerning school plant and supplies. They also attempted to list the personal and professional requirements for successful performance of these activities. While opinion relative to matters of this sort shift from time to time there seems to be a tendency at present, in keeping with the Charters-Waples study, to define the teacher's task to include not merely

Too boisterous in attitude	1	.	1
Unsatisfactory as principal	1	.	.	1
Total number of dismissals: for all reasons	365	554	850	1769

Of the 1,769 reasons for dismissal of teachers and administrators, 332, or 18.8% were for personal deficiencies. Of these 40.7% were for lack of leadership; 21.4% for lack of refinement; 18.4% for lack of cooperation; 10.2% for lack of adaptability; 4.8% for lack of industry; and 4.5% for lack of honesty.

the direction of learning (curricular and extra-curricular), but many other activities as well. Other data defining the scope of the teacher's responsibilities and setting forth the conditions for efficiency will be found in studies of the reasons for failure in teaching, studies of the difficulties of teachers, studies of the likes and dislikes of pupils, studies of the characteristic differences in the teaching performance of good and poor teachers and the many measurements studies to be reported later. Only a few of the studies can be referred to here. Those that are cited have been chosen to illustrate the type of work that has been undertaken in this area. They should also add concreteness to the discussion to follow.

Simon's Study of Reasons for the Dismissal of Teachers from Small School Systems. Simon (26) obtained by interview with 87 county and 81 town superintendents of Indiana, the causes of teacher withdrawals from small school systems for the years 1927 to 1933. Weakness in discipline was the most frequently mentioned cause (Table I). Other frequently mentioned

causes were lack of cooperation, lack of personality; too much attention to the opposite sex, and immorality; lack of adaptability; tactlessness and unpopularity with pupils.

Hill's Summary of Studies in the Difficulties of Teachers. There have been many studies made of the difficulties of teachers. Hill (19) has brought together in one analysis 47 of these studies involving some 12,372 teachers. The difficulties most frequently mentioned in these studies were: providing for individual differences, teaching methods, discipline, motivation, direction of study, classroom management, selecting subject matter, organizing the materials of instruction, planning assignments, grading, testing and the like.

Hart's Study of the Opinions of Pupils. One of the most elaborate studies of the opinions of pupils was made by Hart (18). Questionnaires were sent to the seniors of sixty-six high schools in widely distributed sections of the country asking them to list the reasons for liking their one best teacher most and for liking least their one most disliked teacher. Some ten thousand

TABLE II

Most Frequently Mentioned Instructional Difficulties of Teachers
(An analysis of 47 studies of some 12,372 teachers)

1. Difficulties in providing for individual differences among pupils	19*
2. Difficulties in teaching method	18
3. Difficulties of discipline control, social development of the pupil	17
4. Difficulties of motivation, getting children interested, getting them to work	12
5. Difficulties in the direction of study	9
6. Difficulties in organizing and administering the classroom	8
7. Difficulties in selecting appropriate subject matter	6
8. Lack of time during the school day for all the things that need to be done	6
9. Difficulties in organization of materials	6
10. Difficulties in planning and making assignments	5
11. Difficulties in grading and promotion of pupils	5
12. Inadequacy of supplies and materials	4
13. Difficulties in testing and evaluating	4
14. Personal difficulties of the teacher	4
15. Difficulties arising from conditions of work	3
16. Difficulties involved in diagnosing and correcting particular pupil difficulties	3
17. Difficulties in teaching reading	3
18. Difficulties in making plans for teaching	3
19. Difficulties in promoting desirable habits	2
20. Difficulties in securing study aids	2
21. Difficulty in securing pupil participation	2
22. Difficulty because pupils talk while others are reciting	2
23. Outside interruptions of class work	2
24. Miscellaneous problems mentioned in only one study	40†

* Number of studies in which difficulty was among the first six.

† These were mostly specific problems. Seven were difficulties in teaching this or that subject. Others were rural school problems such as "only one pupil in grade," or "too many grades in one room."

usable replies were received. The qualities of merit in the teachers they liked most (Table III) were: helpful with school work, good natured, friendly, interested in pupils, makes work interesting, has good control, impartial, not crabby, pupils learn subject, good personality and many other similar matters. Among the

reasons most frequently mentioned for the least liked teachers were: crabby, not helpful with school work, has "pets," is aloof, unreasonable, unfair, inconsiderate, has poor control, and lacks interest in work.

Bart's Study of the Teaching Performance of Good and Poor Teachers. Another source of

TABLE III

Reasons for Liking "Teacher A" Best, Arranged in Order of Frequency of Mention,
As Reported by 3,725 High School Seniors

Reasons for Liking "Teacher A" Best	Frequency of Mention	Rank
Is helpful with school work, explains lessons and assignments clearly, and uses examples in teaching	1950	1
Cheerful, happy, good-natured, jolly, has a sense of humor, and can take a joke..	1429	2
Human, friendly, companionable, "one of us"	1024	3
Interested in and understands pupils	937	4
Makes work interesting, creates a desire to work, makes class work a pleasure...	805	5
Strict, has control of the class, commands respect	753	6
Impartial, shows no favoritism, has no "pets"	695	7
Not cross, crabby, grouchy, nagging, or sarcastic	613	8
"We learned the subject"	538	9
A pleasing personality	504	10
Patient, kindly, sympathetic	485	11
Fair in marking and grading, fair in giving examinations and tests	475	12
Fair and square in dealing with pupils, has good discipline	316	13
Requires that work be done properly and promptly, makes you work	364	14
Considerate of pupils' feelings in the presence of the class, courteous, makes you feel at ease	362	15
Knows the subject and knows how to put it over	357	16
Respects pupils' opinions, invites discussion in class	267	17
Not superior, aloof, "high hat," does not pretend to know everything	216	18
Is reasonable, not too strict or "hard-boiled"	199	19
Assignments reasonable	191	20.5
Helpful with students' personal problems, including matters outside of class work..	191	20.5
Dresses attractively, appropriately, neatly, and in good taste	146	22
Young	121	23
Work well planned, knows what class is to do	110	24
Enthusiastically interested in teaching	108	25
Gives students a fair chance to make up work	97	26
Home-work assignments reasonable	96	27
Recognizes individual differences in ability	86	28
Frank, "straight from the shoulder," a straight shooter	78	29.5
Personally attractive, good-looking	78	29.5
Teaches more than the subject	74	31
Interested in school activities	68	32
Sticks to the subject	52	34
Modern	52	34
Sweet and gentle	50	35.5
Pleasing voice	50	35.5
Intelligent	42	37
Prompt and business like	41	38
Sincere	36	39
Knows more than the subject	32	40
Has pep	31	41
Uses good judgment	22	42
Cultured and refined	20	43

TABLE IV

Reasons for Liking "Teacher Z" Least, Arranged in Order of Frequency of Mention,
As Reported by 3,725 High School Seniors

Reasons for Liking "Teacher Z" Least	Frequency of Mention	Rank
Too cross, crabby, grouchy, never smiles, nagging, sarcastic, loses temper, "flies off the handle"	1708	1
Not helpful with school work, does not explain lessons and assignments, not clear, work not planned	1025	2
Partial, has "pets" or favored students, and "picks on certain pupils"	859	3
Superior, aloof, haughty, "snooty," overbearing, does not know you out of class...	775	4
Mean, unreasonable, "hard boiled," intolerant, ill mannered, too strict, makes life miserable	652	5
Unfair in marking and grading, unfair in tests and examinations	614	6
Inconsiderate of pupils' feelings, bawls out pupils in the presence of classmates, pupils are afraid and ill at ease and dread class	551	7
Not interested in pupils and does not understand them	442	8
Unreasonable assignments and home work	350	9
Too loose in discipline, no control of class, does not command respect	313	10
Does not stick to the subject, brings in too many irrelevant personal matters, talks too much	301	11
"We did not learn what we were supposed to"	275	12
Dull, stupid, and uninteresting	275	13
Too old-fashioned, too old to be teaching	224	14
Not "Fair and square" in dealing with pupils	203	15
Knows the subject but "can't put it over"	193	16
Does not hold to standards, is careless and slipshod in her work	190	17
Too exacting, too hard, gives no chance to make up work	183	18
Does not know the subject	170	19
Does not respect pupils' judgments or opinions	133	20
Too changeable, inconsistent, unreliable	122	21
Lazy, not interested in teaching	115	22
Not friendly, not companionable	98	23
Shows boy or girl favoritism	95	24
Dresses unattractively or in bad taste	92	25
Weak personality	85	26
Insincere	75	27
Personally unattractive	65	28
Does not recognize individual differences in pupils	64	29
Voice not pleasant	63	30

ideas on the scope of the teacher's responsibility and the conditions for efficiency will be found in the studies of the teaching performance of good and poor teachers. Barr's (4) study of the Characteristic Differences in the teaching performance of good and poor teachers of the social studies has been chosen as illustrative of the studies of this sort. To get information on this subject Barr made intensive studies of the teaching performance of forty-seven good and forty-seven poor teachers of the social studies through the use of detailed check lists, time chart records, stenographic reports, and repeated observations. Lists of the characteristics most frequently associated with good and poor teachers are given below:

CHARACTERISTICS MOST FREQUENTLY ASSOCIATED WITH GOOD TEACHERS

1. Ability to stimulate interest
2. Wealth of commentarial statements
3. Attention to pupils while reciting
4. An effective organization of subject matter
5. Well-developed assignments
6. Use of illustrative materials
7. Provision for individual differences
8. Effective methods of appraising the work of pupils
9. Freedom from disciplinary difficulties
10. Knowledge of subject matter
11. Knowledge of the objectives of education
12. Conversational manner in teaching

13. Frequent use of the experiences of pupils
14. An appreciative attitude, evidenced by the teacher's nods, comments, and smiles
15. Skill in asking questions
16. Definite directions for study
17. Skill in measuring results
18. Willingness to experiment

SOME ELEMENTS OF WEAKNESS FOUND IN THE TEACHING OF POOR TEACHERS

1. Inadequate provision for individual differences
2. Inadequate socialization
3. Formal textbook teaching
4. Inability to stimulate interest
5. Weak discipline.
6. Inadequate daily preparation
7. Lack of interest in work
8. Inadequate knowledge of subject matter

OTHER LESS FREQUENTLY MENTIONED ELEMENTS OF WEAKNESS FOUND IN THE TEACHING OF POOR TEACHERS

1. No systematic method of checking work
2. Dictatorial, aroused antagonism
3. Drills uninteresting
4. English (not good)
5. Enunciation poor
6. Expected too much of pupils
7. Failed to get results
8. Failed to gain respect of pupils
9. Favoritism toward individual members of class
10. Giggles (peculiar mannerism)
11. Overuse of group response
12. Interpretation (poor, verbose, not easily understood)
13. Indifferent to criticism
14. Lacked ability to organize work
15. Lacked human contacts
16. Lacked knowledge of details
17. Lacked tact in handling disciplinary situations
18. Laughed at pupils' mistakes
19. Loafed
20. Made too much of pupil-response
21. Pupil mistakes and errors not corrected
22. Modest to point of shyness
23. Nagged pupils
24. Nervous (coughed frequently)
25. No understanding of pupils
26. Overemphasized details
27. Too much notebook work

28. Too anxious to please
29. Teacher completely eliminated herself (read morning paper while class recited)
30. Poor relations between pupils and teacher.
31. No use made of pupil experience
32. Pupils didn't know, just plain guessing
33. Pupils not held to careful statements
34. Lacked control over technique of questioning
35. Talked too fast
36. Talked down to pupils
37. Did not talk loud enough
38. Teacher limp, passive, and embarrassed
39. Teacher resorted to bluffing
40. Teacher too friendly with boys
41. Teacher too friendly with girls
42. Teacher's relation with older boys not good
43. Teacher and community not cooperating
44. Unstable in likes and dislikes of pupils
45. Verbose and abstract
46. Walked rapidly up and down
47. Would not take suggestions
48. Wasted time

An Analysis of Teacher Rating Scales. Barr and Emans (10) made an analysis of 209 rating scales to determine those qualities most uniformly expected of teachers by various rating officials. Among the things most frequently mentioned in the teacher rating scales here studied were classroom management, instructional skill, personal fitness and results. A summary of their analysis is given in Table V. A comparison of the data secured relative to the personal prerequisites to teaching efficiency with that of the Charter-Waples study is presented in Table VI.

THE MEASUREMENT OF TEACHING EFFICIENCY

Four approaches have been made to the measurement of teaching efficiency:

- (1) the measurement of traits or qualities of the person thought to be associated with efficiency.
- (2) the measurement of the mental prerequisites to teaching efficiency: knowledges, skills, attitudes, ideals and the like.
- (3) the evaluation of performance.
- (4) the measurement of pupil changes attributed to teaching.

Each of these approaches has its advantages and disadvantages and serves a different purpose. Before going into this matter it would seem

TABLE V

A Typical Scale for the Rating of Teachers *

	Frequency
I. Classroom Management (general) (2, 107, 116, 168)	205
1. Attention to physical conditions	
(a) Heat (45, 167, 171)	48
(b) Light (46, 160, 175)	49
(c) Ventilation (42, 145, 150)	58
2. Housekeeping and appearance of room (7, 97, 119, 148, 152)	173
3. Discipline (6, 137, 138, 179, 184, 188)	160
4. Economy of time (50)	34
5. Records and reports (43, 70)	67
6. Attention to routine matters (31, 162, 173, 197)	72
II. Instruction Skill (general) (1, 47, 89, 118, 133, 143, 157, 198)	371
1. Selection and organization of subject matter (4, 87, 165)	177
2. Definiteness of aim (15, 109, 161)	110
3. Skill in assignment (14, 127, 128, 174)	118
4. Attention to individual needs (26, 182)	70
5. Skill in motivating work (27, 131)	78
6. Attention to routine matters (31, 162, 183, 197)	72
7. Skill in directing study (30, 199)	65
8. Skill in stimulating thought (40)	35
9. Daily preparation (lesson planning) (21, 52, 154, 192)	116
10. Skill in presenting subject matter (60, 87)	54
11. Pupil interest and attention (91)	22
12. Pupil participation (56, 176)	38
13. Attitude of pupils (75, 76, 181)	56
14. Results (in one form or another) (22, 29, 41, 51, 83, 111, 126, 140, 147, 153, 159, 166, 191)	305
III. Personal Fitness for Teaching (general) (5, 18, 33, 88, 117, 125, 129, 142, 149, 189) ..	369
1. Accuracy (carefulness, definiteness, thoroughness) (54, 180)	37
2. Adaptability (48, 65)	64
3. Attitude toward criticism (67)	28
4. Considerateness (appreciativeness, courtesy, kindness, sympathy, tactfulness, unselfishness) (16, 73, 80, 122)	145
5. Energy and vitality (53, 135, 144)	55
6. Enthusiasm (alertness, animation, inspiration, spontaneity) (23)	67
7. Fairness (sense of justice) (77, 82)	49
8. Forcefulness (courage, decisiveness, firmness, independence, purposefulness) (186) ..	5
9. Good judgment (discretion, foresight, insight, intelligence) (63)	30
10. Health (10, 187)	106
11. Honesty (integrity, dependability, reliability) (59, 120)	46
12. Industry (patience, perseverance) (39)	46
13. Leadership (initiative, self-confidence, self-reliance) (17, 57, 96)	131
14. Loyalty	x
15. Morality (92, 101, 123)	56
16. Open mindedness	x
17. Optimism (cheerfulness, pleasantness, sense of humor, wittiness) (86, 112, 124)	54
18. Originality (imaginativeness, resourcefulness) (36, 141)	58
19. Personal appearance (8, 64, 84, 85, 106)	213
20. Posture (190)	5
21. Progressiveness (ambition) (121)	15
22. Promptness (dispatch, punctuality) (20, 98, 103)	112
23. Refinement (conventionality, good taste, modesty, simplicity)	x
24. Self-control (calmness, dignity, poise, reserve, sobriety) (28, 95)	83
25. Skill in expression (13, 169)	93
26. Sociability (33)	52

* The numbers in parentheses following each quality or trait refer to numbers of items in the original study. The data are presented in this manner to enable the reader to check the adequacy of the classification employed.

A Typical Scale for the Rating of Teachers

	Frequency
27. Thrift	x
28. Understanding of children (90)	23
29. Voice (pleasing) (11)	96
IV. Scholarship and Professional Preparation (24, 35, 38, 40, 100, 110, 130, 134, 155, 158, 163, 173, 193)	301
V. Effort towards Improvement (32, 62, 139, 195)	98
VI. Interest in Work—pupils, patrons, subjects taught, etc. (37, 69, 72, 94, 102, 113, 172, 185)	172
VII. Ability to Cooperate with Others (9, 55, 58, 74, 93, 132, 146)	235

worthwhile, however, to emphasize the fact that the measurement of teaching efficiency is fundamental to the study of many aspects of teaching. The scientific study of such problems as selection, recruitment, guidance, education, placement, certification, merit salary scales and supervision all rest upon the development of adequate measures of teaching efficiency. Until this is done decisions about many important aspects of the educational program must rest upon personal opinion, estimates, and

guesses. Such opinions based as they are upon varying conceptions of what constitutes good teaching, different conceptions of evidence and different standards of expectancy have been shown to be generally unreliable. (5)

If it is assumed that it is the function of the teacher to promote pupil growth and learning, then only the fourth of the above named approaches to the measurement of teaching efficiency goes directly at the heart of the matter. Measures of the mental prerequisites to teach-

TABLE VI

A Comparison of the Charters and the Barr-Emans Rank of Teachers' Traits

Traits	Ranks (Charters)	Ranks (Barr-Emans)
1. Adaptability	7	13
2. Attractiveness, personal appearance	13	3
3. Breadth of interest (interest in community, interest in profession, interest in pupils)	8	4
4. Carefulness (accuracy, definiteness, thoroughness)	12	18
5. Considerateness (appreciativeness, courtesy, kindness, sympathy, tact, unselfishness)	5	5
6. Cooperation (helpfulness, loyalty)	11	1
7. Dependability (consistency)	22	19
8. Enthusiasm (alertness, animation, inspiration, spontaneity)	6	12
9. Fluency	24	9
10. Forcefulness (courage, decisiveness, firmness, independence, purposefulness)	12	23
11. Good judgment (discretion, foresight, insight, intelligence)	3	20
12. Health	13	8
13. Honesty	8	22.5
14. Industry (patience, perseverance)	14	17
15. Leadership (initiative, self-confidence)	12	6
16. Magnetism (approachability, cheerfulness, optimism, pleasantness, sense of humor, sociability, pleasing voice, wittiness)	6	2
17. Neatness (cleanliness)	14	21
18. Open-mindedness	20	24.5
19. Originality (imaginativeness, resourcefulness)	14	14
20. Progressiveness (ambition)	22	22.5
21. Promptness (dispatch, punctuality)	19	7
22. Refinement (conventionality, good taste, modesty, morality, simplicity) ..	11	15
23. Scholarship (intellectual curiosity)	17	10
24. Self-control (calmness, dignity, poise, reserve, sobriety)	4	11
25. Thrift	25	24.5

ing success and of the qualities commonly associated with teaching efficiency have value as measures of teaching efficiency only where they have been validated against pupil growth and learning or other acceptable criteria of teaching efficiency. (5) When so validated, measurements of these background abilities supply important data relative to the measurement of teacher growth and in the diagnosis of teacher deficiencies. Measures of performance serve to localize difficulties and, when considered in relation to pupil change, shed light upon the effectiveness of different forms of teacher behavior, but in many instances in studying the psychology of teaching it is necessary to work back from measurable pupil changes to associated teacher activities to the determiners of human behavior.

Evaluation of performance. Contrary to lay opinion acts are not good or bad in and of themselves divorced from purposes, persons, principles, and limiting aspects of the learning-teaching situation (4, 11). Barr (4) has shown that good teaching cannot be differentiated from poor teaching by means of specific teacher activities. Jayne (11) has shown that activities effective under one set of circumstances and for certain purposes may be quite ineffective for other purposes and under other sets of circumstances. Many studies of teaching neglect the *appropriateness* aspect of activities.

Criteria of teaching effectiveness. Three types of criteria have been employed in the validation of measures of teaching efficiency (20): (a) composites of judgments; (b) tests of qualities commonly associated with teaching success; and (c) measures of pupil changes. While the first two sorts of criteria have been frequently employed in the validation of measures of teaching efficiency and ability they are of secondary character and frequently none too well grounded. Gotham (11) has shown that the intercorrelations among these several criteria are not high. Theoretically the most defensible criterion of teaching efficiency should seem to be the measurable changes of pupils under controlled conditions as in experimental research. The application of this criterion has not been easy, however, in practice. (11) It has not been easy: (1) because of the absence of satisfactory measures of pupil growth; (2) because of the difficulties involved in the establishment of adequate controls over factors in pupil growth other than teaching; and (3) because

of the inadequacies of current methods of analysis. Considerable progress has been made in the application of regression techniques in this area (11). Generally the results obtained from research on this subject are no better than the criterion of teaching efficiency employed.

Data gathering devices employed in the study of teachers and teaching. Many different kinds of data gathering devices have been employed in the study of teachers and teaching. Some of the types of devices most frequently employed are: tests, rating scales, check lists, interviews, and questionnaires. Observations may be systematic or incidental, controlled or uncontrolled. Interviews and questionnaires may be standardized or unstandardized. Examples of all of these data gathering devices will be found in the reports to follow.

Studies of the validity and reliability of measures of teaching ability. Many different instruments have been employed in the measurement of teaching efficiency and related abilities (6, 8, 11, 20, 29). Some of these attempt to provide over all evaluations of teaching efficiency, as do some rating scales and some attempt to measure related abilities. Measurements have been attempted of such qualities and mental prerequisites as intelligence, knowledge of subject matter, general cultural background, skill in expression, leadership, teacher pupil relationships, attitudes on social, political and economic issues, attitudes toward teaching and the teaching profession, emotional balance and adjustment, professional judgment, professional information, and teaching aptitude. While considerable progress has been made in the development of tests of one sort or another, particularly for such abilities and mental prerequisites as those enumerated above, chief reliance is still placed in rating scales. Many different kinds of rating scales have been employed such as point scales, quality scales, man to man comparison scales, diagnostic scales and performance scales. By and large, the instruments employed in the measurement of teaching efficiency and related abilities have shown fairly satisfactory reliabilities (6, 8, 20), particularly for group measurements such as made in researches but not for individual measurement. Less success seems to have been achieved in the realm of validity. The reported coefficients of validity seem to fall most frequently in the upper twenties or lower thirties; the reliability

coefficients ordinarily fall in the eighties and nineties (6, 8, 11, 20). The study by Barr and others is probably typical of those in this area. Using a combination of criteria (supervisory ratings, composites of tests of qualities commonly associated with teaching efficiency, and pupil change scores) he secured correlations as follows:

	<i>r</i>
Straper-Engelhardt Teacher Rating Scale.....	.66
Michigan Teacher Rating Scale65
Gain in Raw Score, Stanford Achievement... ..	.57
Schutte Teacher Rating Scale57
Torgerson Teacher Rating Scale55
Pennsylvania Teacher Rating Scale53
Almy-Sorenson Teacher Rating Scale.....	.50
Giles Teacher Rating Scale48

Social Intelligence Test35
Gain in Accomplishment Quotient35
Personality Rating Scale26
General Merit Rankings23
Morris Trait Index L22
Strong Vocational Interest Blank20
Torgerson Teacher Rating Scale (Self-rating) ..	.20
New Stanford Arithmetic Test17
Wood Health Scale04

Many different interpretations have been placed upon the "low" coefficients of correlations found in studies of the validity of different measures of teaching efficiency and related abilities. Some have thought that these low coefficients of correlation indicate a lack of relationship between the qualities and mental prerequisites measured and teaching success; others seem to feel that while the measuring devices may be inadequate, an absence of relationship has not been established (11). Some of the data would seem to support the hypothesis that while no one measure may correlate to any considerable extent with teaching efficiency a number of measures put together through the use of the multiple regression technique may give satisfactory results. The validity of such combinations have been found to vary from .60 to .85 (11). There seems to be a tendency for the multiple *R* to increase as dissimilar measures are added. Unfortunately the error of measurement also increases such that a point of diminishing returns is sooner or later reached as more measures are added.

Some of the measures for which best results have been secured are (11): the American Council Psychological Examination; the Wash-

burne Social Adjustment Inventory, the Torgerson Diagnostic Teacher Rating Scale of instructional activities; the Almy-Sorenson Rating Scale for Teachers, the Michigan Teacher Rating Scale, the Yeager Scale for measuring attitude toward teachers and the teaching profession, the Hartmann Test of the Social Attitudes of Secondary School Teacher, Torgerson Test of Theory and Practice of Mental Hygiene, and Harnly Statements about Education.

The application of factor analysis techniques to this area has not progressed to a point to supply conclusive findings. Hellfritzsch (11) found a tendency for the factors to group themselves according to the type of measure employed: (1) a verbal factor shown by the grouping of scores on paper and pencil tests of qualities commonly associated with teaching efficiency; (2) an acceptability factor shown by the grouping of scores secured from rating of supervisors; (3) a leadership factor shown by the grouping of scores secured from measures of pupil change; (4) an emotional stability factor; and (5) a specific factor.

Among the results most frequently reported for this area, the following are probably typical:

1. More attention needs to be given to the development of the criteria against which various measures of teaching efficiency may be validated.
2. Further studies need to be made of the factors conditioning teaching efficiency and their interrelationships.
3. Teaching is a very human activity; mental balance, personal and social adjustment, teacher-pupil relationship, and personality seem important factors in teaching efficiency.
4. Other factors which seem to be related to teaching efficiency are intelligence, knowledge of the subject, professional judgment and skill in expression.

Prediction of Teaching Efficiency. Considerable effort has been expended on studies of the prediction of teaching efficiency. A large number of factors have been studied, such as: grades in college, intelligence, reading ability, student teaching, leadership, teaching aptitude, study habits, socio-economic status, emotional stability and adjustment, skill in oral and written English, attitudes on social, political, and economic issues, attitudes toward teaching and the teaching profession, social proficiency, pro-

professional information and judgment and various personality traits. The work has been characterized by three very general lacks: (1) an inadequate criterion of teaching efficiency; (2) inadequate measures of the factors studied, and (3) faulty experimental design. Prediction can be made at different stages in the training program, such as at the time of graduation from high school; at the time of entrance upon the program of professional education or at the time of college or university graduation. Prediction may be made of academic success and continuance in college; of success in student teaching; or of success in the field. Studies of all of these problems are important; very few long time studies of prediction have been made, however, wherein measures are applied before training and predictions checked against the criterion of field success.

One of the very real lacks in this area is that of a satisfactory criterion of teaching efficiency. All too frequently the criterion of teaching efficiency has been grades in student teaching or supervisory ratings of teachers in service. While the studies (5) in this area seem to indicate that grades in student teaching correlate with later success in teaching to some extent the correlations are not high. They seem to range from around .06 to .70 depending upon the criterion, the nature of the student teaching and the adequacy of the grading. Supervisory ratings made by a single supervisory official are extremely unreliable (4). Composites of two or more ratings are more stable (11, 12) but may still be quite unsatisfactory. It seems inevitable that preconceived ideas, inadequate or inaccurate data and erroneous conceptions of the nature of efficiency may invalidate personal estimates of teaching efficiency. At least theoretically for the time being the best criteria of teaching efficiency would seem to be found in measured pupil changes with factors in pupil growth other than teaching efficiency held constant by statistical techniques or as in experimental research. This latter ideal is not easily achieved.

For further information on predictions the reader is referred to studies by Barr (12), Kriner (29), Odenweller (20), Sandiford (7, 20, 24), and Ullman (29). Barr (12) reports multiple R's ranging from .60 to .91 for different combinations of measures and different criteria.

The highest zero order coefficients of correlations were found between supervisory ratings and rank in high school graduating class (.29) and predicted grade point average made in the freshman year at the University (.32), university grade point average (.27), grade in practice teaching (.20), prediction of success made by the major department (.38), and prediction of success made by two members of the department of education (.40); the highest zero order coefficients of correlations found between measured pupil changes and such preservice measures as rank in high school graduating class (.69); university grade point average (.53); grade point average in courses in education (.52); prediction of success made by two members of the department of education (.41); general culture test (.23); grade in practice teaching (.21).

In Odenweller's (20) study five hundred and sixty Cleveland teachers, all graduates of the Cleveland School of Education, were ranked by principals, vice principals, and supervisors as to effectiveness in teaching. Correlations were correlated between a composite of ratings and a number of measures: personality (.83); college marks (.29); education marks (.26); student-teaching marks (.19); and psychological marks (.16); age (.15); experience (.15); height (.08); high school marks (.08); handwriting (.06); weight (.02); height-weight ratio (.02); and intelligence (.00).

Kriner (20) using supervisory ratings secured for the four-year college group the following correlations: for the dean's prophecy, .50; for the president's prophecy, .48; for college marks in science, .48; for college student activities, .46; for college marks, .45; for college professional marks, .40; for student teaching marks, .40; for first semester college marks, .23; for college social studies marks, .13. For the two-year group he obtained: for college science marks, .47; for first semester college marks, .42; for the president's prophecy, .42; for the dean's prophecy, .41; for the first two year's college marks, .40; and for student teaching marks, .34. Kriner concluded that teaching success depends upon many factors, the following being the most important: health, intelligence, interest, and leadership. Using supervisory rating made through the use of the Michigan Rating Card, Ullman (29) secured correlations as follows: with social intelligence, .18; with academic in-

telligence, .15; with socio-economic status, .19; with interest in teaching, .02; with academic marks, .30; with professional marks, .30; and with practice teaching, .36.

Sandiford (7) who seems less optimistic than some concludes as follows:

1. Ability of students in teaching is not closely related to intelligence above that necessary for graduation.
2. Ability of students in teaching is not closely related to achievement in special subjects.
3. Ability in practice teaching is not measured by personality tests.
4. The teaching averages obtained in the first term are only a fair index of the final teaching average.
5. Improvement during the period of training is not closely related to intelligence as measured by group tests.
6. If a student has a natural aptitude for teaching, it shows up early.
7. Certain items of information, as determined by a questionnaire, appear to be of value in selecting successful teachers.
8. Ratings of students based on interviews of short duration, even when conducted by a number of raters, are not sufficiently reliable to be used for prognosis.
9. Experienced instructors are unable to segregate effectively those who will prove successful teachers from those who will not.
10. It is easier to select the better students than it is to eliminate the poorer ones.
11. The marks of critic teachers are subject to the variance of individual subjective evaluations.

The research in this area has been in many respects disappointing but with better instruments of measurement, better criteria, and better design better results should be secured. More recent (12) reports in this area would seem to indicate as much.

Selection, Guidance and Placement. Data and techniques such as those described above serve three types of needs that arise in the education of teachers: (1) the choice of criteria for the determination of who shall be admitted to the course for the education of teachers; (2) the validation of concepts and data gathering devices that may be employed in guidance; and

(3) in placement. Such data as are available would seem to suggest that current placement practices are frequently not too well substantiated in fact.

Studies of Factors Conditioning Efficiency. Prediction studies are all in a sense studies of factors conditioning efficiency. There are, however, some studies of factors conditioning teaching efficiency that are not prediction studies. One might, for example, administer to teachers in service a series of measures of intelligence, skill in expression, cultural background, personality, professional judgment and the like and compare the scores obtained from these measures with pupil change to determine how abilities such as these contribute to efficiency. For the time being the purpose is not to validate measures of teaching ability, nor to make predictions but to explore the conditions for efficiency. A very large number of factors have been subjected to study such as age, sex, training, experience, skill in handwriting, skill in reading, height, weight, height-weight ratio, intelligence, scholarship, cultural background, socio-economic status, health, physical fitness, and various traits of personality. Hatcher (28) employing a subjective rating scale of ten personality traits secured coefficients of correlations ranging from .35 to .77 between trait ratings and practice teaching grades; Laycock (28) found no relationships between practice teaching grades and scores on objective tests of personality. Maple (28) secured similar results. Daldy (6) found in a study of the adaptability of domestic science teachers that teachers who experienced difficulty in adaptation showed inability to express themselves definitely, to react quickly to changes in environment, to make contact with their pupils, or to interest them and to concentrate. Over half the group was rated as ill adapted. Rolfe, LaDuke Gotham, and Rostker (11) secured coefficients of correlation ranging from -.31 to +.35 between such tests as the Bernreuter Personality Inventory, the Washburne Social Adjustment Inventory, Morris Trait Index L, the Jackson Test of Social Proficiency and a criterion of measured pupil changes. The correlations between ratings of various personality traits and pupil changes ranged from -.13 to +.43. Engelhart and Tucker (28) found that good judgment, ability to make clear explanations, respect for the opinions of others, sincerity, im-

partiality, firmness, appreciation, interest in pupils, broad mindedness, and knowledge of subject as rated by pupils correlated highest with teaching success.

Davis (28) found that experienced teachers were more successful than beginning teachers but that no relationship seemed to exist between the amount of specialized training possessed by a teacher and the success of his students in state high-school examinations. Stuit (6) found that of successful teachers, 11 per cent had grades below 80, and 19 per cent were above 90; of the inferior, one third were below 80 and 13 per cent above 90. The correlation with teaching success was .31. Coxe and Cornell (28) found no significant relationship between an entrance examination consisting of a

battery of seven objective tests and later success in the field. Rolfe (11) reports low correlations between age, training, and experience and measured pupil gains. Young (6) studied conditions affecting the teaching efficiency of 1,521 Texas high school teachers. He concluded that efficiency is influenced by a number of factors such as training and experience but that other qualities less tangible and more difficult to measure are essential. Leyfirst and Tyndal (28) found significant differences in the scores of pupils taught by good and poor teachers on an objective test in science. Lancelot (20) found significant differences in the persistence and in the quality of work done by students of a given instructor in later courses of a prescribed sequence.

Several studies have been made of professional training, judgment, and information. Using supervisory judgment Knight (4) secured a correlation of .54 for the Knight Aptitude Test, Whitney (4), a correlation of .14 for pro-

fessional marks and Boardman (4) a correlation of .26 for professional information.

Boynton (28) and others studied the emotional stability of teachers and pupils who had been together for two and one-half months

and found that emotionally unstable teachers tend to have associated with them children who tend toward instability, whereas emotionally stable teachers tend to be associated with more emotionally stable pupils. Nichols (28) and others conclude that poorly qualified teachers are detrimental to pupil adjustment.

A summary of a correlation between certain teacher factors and teaching effectiveness as measured by supervisory rating is given in Table VII. A summary of a correlation between certain teacher factors and teaching efficiency as measured by pupil change is given in Table VIII.

Education of Teachers. By and large, educationalists have been more concerned with practices and policies and the curriculum for the education of teachers than with how one learns to teach, individual differences in teaching ability, principles of learning, learning difficulties and the processes of learning for the acquisition of different abilities, skills, knowledges, interests, attitudes, ideals, qualities, and competencies, prerequisites to teaching efficiency. Of the several hundred studies surveyed with reference to the education of teachers none seemed to be primarily concerned with the psychology of learning to teach (21, 22, 23).

Mental Health of Teachers. Considerable attention has been given to the mental health and adjustment of teachers (27). Symonds (8) found that personal problems overshadowed all others, with family relationships, love life, feelings of inferiority and superiority, health, difficulties with teaching, financial problems, making social contacts, and difficulties with superior mentioned most frequently. Hicks (3) found that one-fifth of the women teachers were unduly nervous; that 11 per cent had had nervous breakdowns; that 12 per cent knew they were anemic; that 7 per cent had lung trouble; and that 7 per cent had had heart disease. A psychoneurotic condition was found twice as prevalent among women teachers as among men. O'Malley (3) found many things annoying and irritating to teachers. Peck (3, 20) using questionnaires and tests found that one-third to one-fifth of 100 women teachers studied reported adjustment difficulties. Phillips and Greene (27) found that for single women there was an increase in neuroticism until age thirty and a decline thereafter while with married teachers there was a gradual decline with age. Zach-

ary (3) emphasized the importance of having well-adjusted teachers in our schools. Prescott (20) emphasized the need for studies to determine the extent to which the profession offers adequate opportunities for the satisfaction of basic personal needs of teachers such as freedom from fatigue, marriage, receipt and bestowal of affection, social opportunities, security, full rich experiences, freedom to exercise initiative and creative thinking. Emotional immaturity, lack of adaptive ability, absence of interesting hobbies, and idiosyncrasies resulting from conflict with associates are listed among the most frequent causes of mental ill health (27).

For further discussion of this problem the reader is referred to the bibliographies attached to the following references.

PHENOMENOLOGY.—Phenomenology, the science of phenomena, is a presuppositionless, but systematic, exploration and description of experience, including both acts and contents, both sensuous imagery and disclosed meanings. All sciences, including the science of psychology, take their point of departure from phenomenological descriptions. For example, the psychological study of receptive processes would be impossible apart from phenomenological description of the relationships among different qualities of sensation. The so-called color solid, taste tetrahedron, odor prism, and so forth, represent summaries of phenomenological explorations.

Contemporary phenomenology received a great impetus from the systematic work of E. Husserl, who was a student of Brentano, the Austrian Act psychologist. Brentano, following the Scholastics, had taught that every experience has an object, and every type of act has its terminus in a specific kind of content. Phenomenologists assume that description is logically prior to deliberate categorization and deliberate explanation. Like Descartes, Husserl espouses the ideal of methodical doubt as a first step in all scientific and philosophical work. The given must be described in its full immediacy before its development can be explained, or its status in reality can be determined.

Most serious accounts of creative thinking are essentially phenomenological. Henri Poincaré, the famous French mathematician, has given phenomenological descriptions of mathematical reasoning, and T. Ribot, French psychologist, has described the experienced stages in various processes of mechanical invention. Leone Vivante, an Italian phenomenologist, has stated that creative solutions to problems occasionally transcend all the ordinary principles of association. Such achievements require unique schemata of comprehensibility. They do not conform with average or conventional schemata. Perhaps only a genius could appreciate the creative experiences of another genius, and the attempt to explain them would be even more difficult. The height of folly would be to attempt to explain something which one has heard mentioned but which one has experienced in no sense more direct than the verbal.

Certain psychopathologists have done essentially phenomenological work. Freud, Zilboorg,

and especially Jung are among those psychopathologists who have insisted that the content of abnormal mental processes must be understood in order to achieve a basis for adequate diagnostic and therapeutic work. Some phenomenologically inclined psychopathologists have noted that inner happiness is enjoyed only insofar as positive values in an experienced world predominate over negative values. Self-evaluation and world evaluation are components of a unitary process. In an inimical world the person evinces inflated egoism or extreme aggressive attitudes. If there is no basis in a personal world for faith and hope there is also no basis for humility and charity. If egoism and aggression predominate, anxiety and guilt feelings are also evident. These are not moral judgments, but rather are generalizations from many phenomenological descriptions of the content of the personal worlds of mal-adjusted people. Yet perhaps some moral judgments are founded upon such factual generalizations.

J. J. Rousseau made some generalizations which perhaps could be reduced to a broadly observable phenomenological basis despite the fact that many critics have considered his thoughts to be arbitrary. Rousseau stated that only the natural man is happy. Possibly contemporary observers of human experience are in a better position than Rousseau to test such a generalization. Some have maintained that the increasing proportion of mechanical artifacts and other inorganic objects in the contemporary urban environment is accompanied by deterioration in characteristic personal moods. Living creatures other than human beings are increasingly excluded from the typical life space of modern man. As time passes fewer people with memories of surroundings which present a great plenum of living orders remain present to enhance the tone of urban existence. The diversification of values continues, and this is called "progress." At the same time the human sense of a basic, all-embracing value, which might be called the life value, is being lost. If these generalizations are correct, or even if they only dimly reflect the basic human situation, some practical implications of them should be investigated by applied psychologists and social engineers generally. Experiments in building communities which offer the participants a blend of urban and rural experiences

should be initiated. The confusion between a rational, social control of some natural processes through cooperative exploitation of a technology, on the one hand, and complete alienation from the old sense of kinship with nature, on the other hand, may be one of those confusions which are responsible for the increasing cynicism and hatred in so many contemporary life experiences.

A phenomenologist may describe systematically any person's direct experience in its totality. Each individual may know and describe his own experience by means of introspection, but knows other persons' experience through some medium of their expression. The phenomenologist does not prejudge the problem as to whether a systematic knowledge of one's own experience is easier to attain than a systematic knowledge of another's experience. Although a person experiences just what he experiences, it by no means follows from this by any logical necessity that the person must attain a systematic knowledge of the contents of his own experience. Phenomenology, whether referring to internal or external experiences, is a task. Systematic knowledge of the directly experienced is itself an end product of phenomenological exploration.

Integral phenomenology is the systematic exploration and description of personal worlds. It describes that which appears in the various streams of consciousness. Whether these systems of experience are utterly discontinuous is another question which the phenomenologist would not prejudge. Such concepts as that of quantitative or qualitative monism or pluralism are philosophical constructs and are beyond the scope of phenomenology. The phenomenologist may note relative continuities, or discontinuities, but he does not speculate about ultimates. Phenomenological description provides a legitimate basis, however, for scientific theorizing or for philosophical speculation.

A phenomenological description of a continuum of behavior would provide a basis for psychological theorizing. In the phenomenological description both actions and consequences, productive processes and consequent products would be described just as they are directly experienced. Some continua of behavior provide no self-evident basis for drawing a distinction between deed and consequence, creative act and created result. Similarity, some

social behavior, such as the cooperative production of goods might show results the precise individual contributions to which would not be self-evident. To the phenomenologist, unity in the product might be more conspicuous than any diversity which were determined by the multiplicity of cooperating productive workers. The individual contributions might be merged in a common effect. If certain psychologists preassume that there must be a complete dichotomy between person and expression, on the one hand, and between the personal and the collective, on the other hand, that assumption reflects simply the interests of theory and is not necessitated by all direct experiences of behavior. Like all specializing sciences, psychology sometimes tends to distort given situations of experience, if only by positing arbitrary divisions or arbitrary outer boundaries. Thus many scientific data are partly constructs. Such construction may, or may not, lead to errors in the consequent theorizing. The phenomenologist believes, though, that the scientific specialist clearly should understand at just what points and in just what respects his data have distorted the original phenomenological evidence.

A phenomenological description of cultural artifacts would go beyond objectivistic functionalism, such as that developed by the brilliant theorist Bronislaw Malinowski, since the values of artifacts could only be described insofar as the culture context were experienced in the way that the members of the particular culture experience it. From the phenomenological standpoint, a culture is simply a specific class of personal worlds. The artifact has a value within worlds of one class that is not experienced in other worlds. Similarly, the engineering value of an object differs in different orders of technology despite the fact that some common physical characteristics of it are apparent within the perspectives of all the orders.

A person may interpret himself as being a product as well as being a producer. The psychological subject is both a patient and an agent. Therefore the contexts and imperatives of self-knowledge and self-engineering provide few, if any, exceptions to the above principles concerning phenomenological understanding.

Some personal products are symbolic expressions of the person's quest for broader contexts and more compelling imperatives. Art, litera-

ture and some personal documents are among such products. Through interpreting complex systems of personal expression, phenomenologists may experience the ideology which is proper to a particular personal world or class of personal worlds. The critical problems arising from this last consideration are beyond the scope of this article. (See the article on Personal Document Analysis.)

Nicolai Hartmann has pointed out that phenomenology and explanatory science are reciprocally dependent. All scientific hypotheses are imaginative interpretations of phenomenological evidence. In turn the hypothesis may suggest physical operations through which novel experiences are achieved, and novel contents are made available for systematic phenomenological exploration and description.

Phenomenology and logic are also mutually dependent. As Husserl pointed out, the intuition that two plus two equals four remains even when physical combinations of two units with two produce a fifth. Supposing, however, that every physical combination produced a different sum of objects than is actually the case, we should then have a different physical world. And for each physical system a certain basic arithmetic is most fitting. Others may be derived from it.

Like his world, the person is a relative unity. Normal personal experience never conforms to analytic categories. Contents which trace to the past are blended in the present affective unity. Also, every situation which the person experiences contains aspects of his world other than those which are directly related to the purposes which appear in it. To interpret any situation, one must appreciate the series of which it is a member, and such appreciation would complete an integral phenomenology of a great and unique world of affection and reason. Such worlds, no matter how clearly or critically their main internal contrasts are interpreted, may seem exotic or disconcerting just because their independence of one's own personally characteristic imagination is thus indicated. So within the phenomenological universe of discourse solipsism is transcended, and the assurance of participation commences. The reality and something of the value of the fellow-being is experienced directly, and the mockery of abstract scepticism is forthwith overcome. This is the "Open Sesame!" to that limitless social

world, the whole realm of persons; to that for which all science plays a servile role and from which psychological science receives its special imperative to serve man by helping him know and guide himself.

PHILOSOPHICAL PSYCHOLOGY.—

Only slightly more than a century ago, psychology was definitely a part of philosophy and dealt speculatively with some of the central problems of epistemology and metaphysics. Since that time, however, psychology has largely broken with its parental discipline, assumed a considerably more factual and practical position, and assimilated the methods of study and research borrowed from physics, biology and education. As a result of this break, many of our best scholars look askance today at anything smacking of metaphysics or introspection, call philosophical psychology obsolescent and declare, with H. H. Remmers, that "our philosophical inheritance has unfortunately not been an unmixed blessing."

But the ties with the past are strong; moreover, there has really never been a reason to make the break with philosophy excessive. The fact is, anyway, that in quite a few of our colleges the young science is still classified together with philosophy and taught by instructors from the same department. In the Catholic institutions of higher learning it is dominated by the teachings of Aristotle, as interpreted by St. Thomas Aquinas, in which form it constitutes an essential part of neo-scholasticism. Besides, there are numerous psychologists who contend that quantitative research is being over stressed and that the further progress of the science

demands a serious revision of its theoretical foundations, requiring a great deal of skill and vigor in reasoning. Thus, K. Lewin states: "Investigators are coming to feel that a mere piling up of facts can only lead to a chaotic and unproductive situation. . . . Only with the help of theories can one determine interrelationships." In W. Kochler's belief, "too great an interest in present quantitative methods and in their standardization is not a hopeful response to the fact that the development of psychology depends upon the discovery of new methods and problems in the future, and not upon the monotonous repetition of a few standardized methods which fit only primitive problems." According to C. A. Ruckmick, psychology can "well afford to cease its feverish activity in the accumulation of so-called facts and to try again to envisage the forest as a whole." In P. L. Weber's opinion, "the time seems opportune and ripe for a positive reconstruction on a large scale."

The mainstay of philosophical psychology is undoubtedly the formulation, study and analysis of the basic concepts of psychology as a whole. Among the concepts inherited by us from the past but preserving their importance the most prominent are: mind, self, consciousness, and cognition by perception.

The original interpretation of the first of these concepts was that of a metaphysical substance, sometimes confused with the soul. The dualistic theories described mind as an independently existing substance, distinct from matter. According to Descartes' interactionism, the two substances were connected in the pineal gland, "the seat of the soul." Spinoza, however, denied interaction and regarded mind and matter as two of the attributes of the infinite substance, or God. Malebranche saw in the relationship the hand of the Supreme Being, for whom every event in mind or matter offered an occasion for a creative act. The monistic theories, on the other hand, assumed that there is but one substance. The idealists of Platonic descent interpreted matter as mere appearance only misleading human reason. Berkeley came to the conclusion that, as nothing external can be known directly except images, it is superfluous to postulate the existence of anything but perception, human and divine. Leibniz regarded matter as consisting of monads, or little souls, and taught that the relationship between

what exists in space (matter) and what happens in consciousness (mind) rests on the principle of pre-established harmony. During the 18th century there arose considerable opposition to the idealists in a number of materialistic movements, all teaching that mind is a modification or element of material substance. Thus, Cabanis contended that mind is a function of the brain, just as the secretion of bile is a function of the liver. More recent epiphenomenalism of Clifford, T. Huxley and Hodgson interpreted mind as a by-product of physiological processes, a sort of "whistle of a steam engine." The double aspect theory, or identity hypothesis, presented mind as "the other side" of organic matter, but essentially identical with it. Kant's critical idealism and Hegel's objective idealism compromised between dualism and monism, in that the former took an agnostic position with regard to "things-in-themselves," whereas the latter taught that material reality is endowed with the quality of rationality representing the Absolute Idea.

Whereas mind, as a metaphysical substance, is only of historical interest to the psychologists of today, mind, as the sum-total of one's experience, is still of great but somewhat puzzling significance. They cannot accept Hume's position who, having examined his own mental processes and having failed to find introspectively anything but succession of individual experiences, concluded that there was no self. For to them the interpretation of mind as the sum-total of one's experience is inseparable from the notion of self. It is clear indeed that there persists something throughout the many changes of one's life, by virtue of which one calls himself 'I' and distinguishes himself from all other individuals. Depending on the choice of emphasis, this self is identified mainly with the living body and characteristics pertaining to it, in which case we deal with what may be called the physical self; or else it is identified with "the organization of experiences in a dynamic whole," as W. Pillsbury put it, in which case we deal with what may be called the psychological self. The Behaviorists tend to confine the notion to the former, as "the behavior of the human being as a whole," whereas Freud and the psychoanalysts extend the notion even beyond the latter, to include also and mainly "the unconscious mind." In the earlier

psychoanalytic literature, to be sure, the self was treated as essentially synonymous with the ego and stood for the seat of the conscious and self-preservative functions of life. Later, however, the ego came to acquire a more specific significance, namely, to refer to the organized portion of the mind, which is derived from the id and controls voluntary thought and activity as well as the external manifestations of emotional tensions.

In addition to being a persistent and normally growing totality, the self is often understood as subject, in its opposition to objects, or to everything that is "not-me," as described by William James in the following passage: "One great splitting of the whole universe into two halves is made by each of us, and for each of us almost all of the interest attaches to one of the halves; but we all draw the line of division between them in a different place. When I say that we all call the two halves by the same names, and that those names are 'me' and 'not-me' respectively, it will at once be seen what I mean." This meaning of self appears to be so important that, whether recognized or not, it lies at the foundation of all discussions, and actual manifestations of course, of self-interest, egocentrism, egoism, and aggressiveness.

Closely connected with, but distinct from, mind is the concept of consciousness. Some psychologists assert, with J. B. Watson, that "states of consciousness . . . can never become data for science" and that psychology should "discard all references to consciousness." Others point out, with G. M. Stratton, that no scholar realizing "the difficulty of a scientific study of our conscious life" should "give up the fight when it has hardly yet begun" and thus "give over to hopeless ignorance what to many men is the most interesting side of our life." The truth is, however, that the great majority of people find themselves utterly unable to doubt the existence of consciousness. Nevertheless, it is exceedingly hard to define consciousness or to study it. The only well-known but clearly unsatisfactory definition of it is that by Ladd, namely: "Whatever we are when we are awake, as contrasted with what we are when we sink into a profound and dreamless sleep, that is to be conscious." The study of consciousness is seriously aggravated by the fact that it completely excludes objective observation and meas-

urement, except as revealed in its consequences, such as physiological changes, expression, and behavior in general. Introspective findings are bound to remain personal and subjectively significant. But such findings are not, therefore, scientifically worthless, especially with regard to broader generalizations and principles of wide application. It should not be very difficult to agree, for instance, that human experience has two aspects, one observable by outsiders, as behavior, and the other known only to the subject, as his own awareness. The two aspects overlap, in so far as behavior is not necessarily conscious in all of its phases and consciousness is not necessarily observable even in its bodily manifestations. Awareness has been, to be sure, interpreted as a form of behavior, notably by John Dewey and the pragmatists. Bergson, too, contended that "the orientation of our consciousness towards action appears to be the fundamental law of our psychic life." Another point on which there is much agreement is that consciousness is, in William Stern's expression, *unitas multiplex*, a unity with complex and varying contents. If we realize, in addition, that conscious mental processes constitute a progressive succession of states, which can never be completely stopped, we are ready to accept what James designated as "the stream of consciousness" (or thought). As E. G. Boring recently remarked, "the most striking thing about consciousness is its continuous flux and change." Such findings are hardly controversial, except in their particular formulations; and, were it not for our fear and distrust of introspection, it would not be impossible to refine the method to such an extent as to make it one of great scientific value.

The problem of perception is closely connected with that of the knowledge of the external world. Though common sense, or naive realism as it is called in this regard, insists that we are introduced by our senses directly to realities of space, no one has ever been able to show exactly how this is achieved. In fact, ever since Locke demonstrated that there are no innate principles of the mind, it has been acknowledged that the only cognitive experiences the human mind is capable of are perceptions and ideas. In other words, mental operations are confined to mental material. This raises two basic problems, first, what may be

the distinction between elements of the mind and the corresponding outer realities, and second, how cognition can transcend its own boundaries. The former question is answered by the postulate that images of things are existentially and probably qualitatively different from the things themselves, although it is still a moot problem as to precisely what the difference may be; and the latter question presupposes, in L. E. Hahn's words, "passing beyond the 'inner' data to the 'outer' physical world of moving particles." Despite all the speculation and investigation, from Plato's days up to the present, no satisfactory solution of the problems has been obtained. Perception remains largely a mystery, even though it is possible to define it safely as awareness of external objects, events, relations, and qualities. It seems that such awareness depends for its causation on sensations, that is, on processes of stimulation of sense organs and on the transmission of resulting impulses along nerve fibers to brain centers. It is there that awareness of external reality arises, as a result of combined activity of several centers or through what Pavlov called "irradiation." This is a distinctly psychological phenomenon of perception in which images are attributed, or projected, to the source of stimulation, whether it be located inside or on the surface of the body, as in the case of the so-called body senses, or outside the organism, as in the case of the so-called space senses, namely, vision, hearing and smell. This process constitutes, in R. W. Sellars view, an "activity in the reverse direction of that of sensing." Moreover, perception does not leave the images intact, but "interprets" them; that is to say, perception consists largely in selection, organization and modification of the material presented to the mind by sensations.

We have devoted the bulk of this brief discussion to a few basic concepts of historical significance. But the field of philosophical psychology covers all psychological concepts, of course, including those formed in our own days as well as those still in the making. To this group belong, to take a few concepts at random: personality, motivation, adjustment, projection, repression, neurosis, morale, environment, habit, configuration, meaning, extra-sensory perception. None of them has been adequately defined or analyzed, none of them is

sufficiently clear, perhaps because they are still transient in their nature. But they should not be allowed to remain vague, ambiguous or erroneous, as the case may be. It would not do, for instance, to keep on regarding intelligence as that which the intelligence tests measure. We should realize that, in the last analysis, the use of words has its responsibilities in any science. Facts alone will not create sound terminology in psychology. It must correspond to adequate concepts, skillfully selected, grounded in truth, refined by reasoning, and clarified in extensive discussion. This, in short, is the practical function of philosophical psychology, not vague speculation and the language of abstractions.

PHYLOPATHOLOGY.—The terms "*phylobiology*" and "*phylopathology*" refer to behavior and its disorders and were introduced by Trigant Burrow to describe the researches of himself and his associates into these disorders. These investigations, originated by Dr. Burrow, represent a type of behavior-study that is not to be identified with prevailing psychological or psychiatric schools. From the altered frame of phylopathology behavior-disorders are regarded as conditions that reflect a biological disturbance within the organism of individual and phylum. This disturbance involves a dislocation of feeling within the system of the self. It involves an "*affecto-symbolic impasse*" that distorts human relations, both personal and social. The investigation is directed specifically toward determining the neurophysiological substrate of the condition and toward developing practical means of readjusting this maladaptation in its extension throughout the species man.

An understanding of the altered approach of phylopathology to individual and community behavior will be assisted by considering its various aspects in their historical sequence. Burrow, who as a charter member of the American Psychoanalytic Association was one of the first adherents and promoters of psychoanalysis in this country, wrote a number of papers between 1911 and 1918 in which he presented principles that greatly modified and extended the implications of traditional psychoanalysis. Abrogating the view that behavior-disorders are restricted to neurotic patients, he maintained that "normal" behavior embodies a type of adaptation that is also distinctly deviate, that "normality" too contains elements that are self-reverting, substitutive and discrepant. In accordance with this position so-called normal social behavior was included along with neurotic reactions in the material to be investigated.

Observation of the "*social reaction-average*" commonly regarded as normal disclosed the existence of affect-impediments, of "an inherent social disharmony" in man's behavior as a community. It disclosed subterfuges and distortions associated with the tendency in man to center emotional interest upon his own image. The disharmony is thus coterminous with the development in man of self-consciousness. This ethnic mechanism led to a host of behavioral interferences whose social systematization Bur-

row at that time referred to as a "*world neurosis*" or the "*neurosis of the race*." Thenceforth he consistently emphasized the universal distribution of this biological impediment and pointed out that normality, as commonly interpreted, cannot be considered a reliable criterion in the understanding and treatment of neurotic disorders.

In contradistinction to this "normal" mode of adaptation with its self-conscious, ulterior interests and reactions, Burrow drew attention to the evidences of a more basic, unsophisticated, preconative, or "*preconscious phase*" of behavior. He also used the terms "*primary identification*" and "*nest-instinct*" in describing this original organismic phase of solidarity and continuity as it is exemplified in the biological identity between the mother- and infant-organisms. Evidence was presented from the life of normal and neurotic individuals, from poetry, myth and ethnological sources in substantiation of this primary functional pattern. An organic principle of continuity and coördination was sharply differentiated from the self-interested attitude of competition and personal gain that now characterizes normal social interrelations.

This more encompassing outlook led to an altered interpretation of the factors responsible for neurotic conditions. The suppression or interruption of the original mode of man's interrelational adaptation by secondarily acquired, self-preoccupied drives was seen to be the basic factor in the causation of behavioral conflict and neurosis. At the same time Burrow saw in many neurotic manifestations a constructive element, "a protest of man's inherent truth against the duplicities and subterfuges of the normal social program." From this background, what we commonly know as sexuality and its moral repression were regarded as manifestations of the secondary, self-reverting, invidious sphere of adaptation. The readjustment of the neurotic personality to this competitive social norm constituted only a temporary, symptomatic alleviation. Furthermore the psychoanalyst, while maintaining the conventional attitude of professional aloofness, was himself necessarily a participant in man's social unconscious. He too was an inevitable part of this "confederacy of unconsciousness popularly endorsed as normality." Thus it was early found that the fundamental problem consists in a basic conflict between the organism's primary, coördinated

mode of adaptation and a secondary, self-reflexive mode. It was found to consist in man's vain effort to reconcile his developing self-consciousness with his basic functional integration and growth as a conscious social organism.

The method of "group-analysis" which Dr. Burrow later called "phyloanalysis" and which, with the cooperation of his assistant, Mr. Clarence Shields, he introduced and developed in the years following 1918, afforded an opportunity to supplement and bring to practical test his altered concept of the neuroses and of behavioral maladjustments generally. In our laboratory setting the interrelational attitudes and reactions occurring within the group were observed and examined for their underlying content. They were observed not in retrospect but in the actual moment and they specifically included the immediate reactions of the observers themselves. To this end experimental groups met regularly several times a week; they were composed of from four to twenty individuals, both "normal" and "neurotic." In addition, in later years observations which were no less controlled took place in quite informal settings, such as during the meal hour and other routine activities.

Consistent with this procedure, expressions of normal behavior or of the social reaction-average were not necessarily regarded as bona fide but were treated as laboratory material and analyzed with respect to their latent dissociative trends. Manifestations of sympathy or revulsion, of propitiation or irritation, of "liking or disliking," of entrenched authoritarianism or sentimental dependence, of elated or depressed reactions—these and endless similar dichotomies we were obligated to view with objective dispassionateness. Further, these alternating responses and the kindred behavior-fluctuations that make up man's dynamically interrelated system of social interchange were not treated as isolated incidents characterizing this or that specific individual. They were regarded, instead, as symptomatic expressions of a disorder that affects man as a community or "*phylo-organism*," and from this broader organismic perspective we sought to determine the common denominator that inheres in this vast complex of behavior deviations.

These findings corroborated Burrow's earlier observation of a secondary, distorted motivation extending throughout the behavior of man

as a species. Everywhere the activities of individual and group showed evidence of the disturbing influence of a spurious self-image or "*I-persona*" and its social projections. An unconscious addition to "*social images*"—a disposition to arbitrary phantasy-formations which have become socially systematized—was seen to exert a disorganizing influence upon man's interreactions generally. This distortion of primary feeling-processes through their false attachment to the symbol has resulted in a medley of behavioral symptoms: in fear and self-defense, in insecurity and competitive aggression, in guilt and its inevitable over-compensations, in obsessive acquisitiveness—personal, sexual, social, political, religious, economic—and its moralistic disguises. These symptoms of "*the social neurosis*" were found to be an inseparable part of our "normal" behavior, irrespective of personal and cultural variations. They were found to constitute a continuous reaction-tissue which interweaves with prevalent patterns of socially accepted codes and mores. Such socially conditioning forces corroborate the secret autocracy and antagonism of the "*I-persona*" and thus stimulate and maintain disordered community function. In brief, the social neurosis was seen to consist of a correlation of individual and social symptoms, whether expressed in the presumably well-adapted personality, in the substitutions and inhibitions of neurotic tendencies, in the antisocial and destructive trends of war and criminal reactions, or in the imbalances and maladjustments of our economic, industrial and political life.

We must conceive of a phylogenetic miscarriage of function through which man's affective images have become so widely systematized socially as now to function independently of the organism's basic behavioral assets. The symbolic part-function, while invaluable in man's internal economy and in his daily management of the environment, has misappropriated the phyloorganism's essential feeling-processes, diverting them into spurious self-interests or "*partitive*" motivations that possess no biological value for the organism as a functioning unit but that, on the contrary, obstruct an adjustment consistent with the laws of the phyloorganism as a whole.

Early group-analytic observation of these behavioral inadequacies in individual and community led to certain modifications in the ex-

ternal reactions of the participants, to a mitigation of secondary neurotic symptoms and of obvious antipathetic trends. But the underlying phylic disturbance expressed in the symptoms of the social neurosis—the esoteric absolutism of the "I"-persona with its social projections—remained undissolved. That is, the inevitable social systematization of our experimental setup, because of habitual autocratic community preconceptions, still tended to obstruct even the process of observation and to oppose a powerful barrier to consistent analytic investigation. With continued experimentation and growing insight into phylic processes we became aware of the impossibility of reaching a more basic adjustment through mere "socio-symbolic" procedures. The realization of this impasse was naturally a frustrating experience but it forced our investigation toward the more basic aspects of man's interrelational maladaptations.

In the process of phyloanalysis Burrow had earlier observed in himself the presence of a physiological stress or tension in the frontal and ocular regions—a tension which he found increasingly to be associated with the incidence of affective trends. This observation furnished the clue to an altered basis of procedure. For with the recognition of this physiological stress there came about a coincident awareness of the organism as a total entity. So that we ceased thereafter to pursue the analysis of the secondary resultants of affecto-symbolic behavior, whether enacted or fancied. Attention was directed now toward intrinsic bionomic processes, specifically toward the discrimination of patterns of tension perceptible within the organism. Investigation was occupied with the internal conflict between the circumscribed pattern of the affecto-symbolic segment and the pattern of reaction of the total organism. It gradually became clear that the neuromuscular tensions involved in the formation of affect-images were coterminous with the systematization of tensions embodied in the "I"-persona. It was possible to make out experimentally that the tensions characterizing the "I"-persona have their seat in the forepart of the head and in the region of the eyes. With practiced observation the organism's localized pattern could now be more or less sharply differentiated from the tensional pattern of the organism as a whole. From the background of the total organismic pattern it became possible to sense and observe

the limited pattern of the "I"-persona and its socially conditioned behavioral resultants. It is therefore the thesis of phylobiology that the interference or conflict between two irreconcilable tensional patterns constitutes the organismic denominator to which disorders of behavior must ultimately be referred.

Through this experimental technique there developed a modification in internal constellations in which the organism was able to recognize with increasing consistency the physiological difference between the motivation of the total pattern of behavior and that of the specific partial pattern. With this fundamental readjustment, there occurred an automatic shift in the customary process of attention or adaptation in relation to the environment. An altered mode of attention became operative, and this mode Burrow called "*cotention*," contrasting it with "*ditation*" or the self-interested partitive attention of normal adaptation. Coincident with cotention there was the reassertion of a "*central constant of motivation*" whose function is phylogenetically prior to that of the system of affect-images with which psychiatry, psychoanalysis and "normal" pedagogic methods habitually deal. This approach entailed a complete reorientation in organism-environment relationships, a change which deeply affected interrelational feeling and behavior. Conflict and disorder as they influence the customary reactions of individual and group took on an altered meaning. From the cotentive frame of reference the pathology of the "I"-persona stood out in clear relief as a condition characteristic of man throughout. From the background of this larger pattern the symptoms of the social neurosis, or of habitual ditation, were seen as universal, phylic phenomena.

In a word, cotention makes possible the clarification and readjustment of accustomed processes of feeling and thinking. It makes possible the realization of the phyloörganism's primary coördination as well as of the contrast between this configuration and the many behavioral distortions of both "neurotic" and so-called normal social manifestations. The localized affecto-symbolic or ditentive pattern loses its stress and urgency—a consummation which was found to outlast the immediate experimental periods. Concomitantly there is the disappearance of habitual self-centered preoccupations. Affect-images are dissolved, the symbol is restored to

its proper place within the functional coordination of the total organism, and a more direct interaction between organism and environment comes into its own. This reorientation of outlook, of motive and of action becomes effectual in everyday activities and brings the social level of behavior more and more into alignment with man's primary phylic function.

It was of special interest to observe that the differentiation between the two patterns of behavior, ditionation and cotention, is accompanied by specific physiological modifications recordable by appropriate instrumental methods. On the basis of this differentiation various physiological functions were submitted to experimental investigation. We found that on shifting to the cotentive pattern there immediately occurred a marked slowing of respiration. This slowing of respiration from an average of 12-14 per minute in ditionation to an average of 3-6 in cotention was consistent. Another series of alterations had to do with eye-movements. We observed a marked decrease in the frequency and in the range of eye-movements during cotention. But observations of this feature by means of an especially devised photographic apparatus are still in progress. In addition, a study of the electrical brain potentials, amplified by the Grass method of frequency analysis, showed that in cotention there is a decrease in the alpha-component and in the amplitude of the brain-waves.

These physiological modifications support the evidence that the internal reaction-shift coincident with cotention involves basic neurophysiological factors. The physiological changes observed in ditionation and cotention as well as the behavioral processes involved are related both to the cortical and to the basal areas of the brain. The close connection, therefore, between behavioral and physiological features is not surprising. This interconnection and the recordable nature of these factors remove the investigation of behavior-disorders from the realm of mere inference and speculation, and place it upon a concrete objective basis.

The principle of organismic integration or coordination which phylobiology applies to man's social interrelations constitutes an extension of the *principle of primary identification* or of the *preconscious mode* posited by Burrow in his early formulations regarding the organism's ontogenetic continuity and coordination.

Subsequent experimental differentiation of internal tensional patterns reactivated these primary organismic assets and brought them to pragmatic operation. Reports on the structural and functional coordination of the living organism as observed in other biological fields further strengthen the evidence of this onto- and phybiological principle.

It need hardly be emphasized that the various types of group therapy that have arisen in recent years differ radically from the scope and procedure of phyloanalysis. While Burrow's work undoubtedly gave the original stimulus to various group developments, none of these subsequent "group" procedures envisage a reorientation that is fundamental and "neurodynamic." They do not envisage the presence of a widespread "phyloneurosis," nor does the psychotherapist recognize his own involvement in it. He merely makes use of accustomed social standards, of which he too is necessarily an unconscious part, in order to accommodate the patient to the accepted social norm. It is the position of phylobiology, on the other hand, that the individual who represents the customary norm or the average social reaction deviates from a scientifically determined biological norm no less than does the maladapted patient.

The researches of phylobiology are sponsored by The Lifwynn Foundation of which Dr. Burrow is Scientific Director. The Foundation is a membership organization which was incorporated in 1927 for the purpose of carrying on these investigations in behavior-disorders and affording the appropriate community basis for their study and adjustment. The Foundation is maintained by voluntary contributions.

POINTS OF VIEW.—*Components of psychological theorizing.* As in other disciplines, theoretical contemplation and organization in psychology serve primarily two purposes: to prepare as well as to interconnect observations which otherwise would be, or appear to be, unrelated or incidental. In this endeavor, carefully defined or elucidated *concepts* are combined to form *hypotheses, postulates, or laws*—depending upon the degree of tentativeness and of empirical confirmation—and these in turn are woven into *theories* of greater or lesser comprehensiveness.

Most of the major theoretical efforts in the psychology of the past climaxed by developing into backbones of *schools or systems*. Such a development hinges upon claims of universal applicability of the underlying theoretical principles and leads to their expansion over wide areas of psychology. This process is frequently characterized by an emotional investment that in itself seems sufficient explanation for the strong assertive emphasis usually associated with schools. Theory then becomes a powerful propagandistic policy making agent directing

future research activities over and above its original synoptic function.

The chief difficulty of schools lies in the fact that they usually are inseparably entwined with the specific character of the *field* of research in which their major theories or principles were originally developed, and that none of the principles suggested has so far positively proved its worth in carrying the full explanatory load imposed upon it by its exponents. Attempts to generally subsume the functioning of behavior under the phenomenon of conditioning (as in classical behaviorism), or under the phenomenon of closure of perceptual patterns (as in Gestalt psychology), may serve as illustrations. The maturing psychology of the present tends somewhat to de-glamorize the youthful enthusiasm, singleness of purpose, and the search for ultimates inherent in the founding of all-inclusive schools, leaving room for a multiplicity of quasi-basic principles and thus paving the way for an integration of schools into a unified family of parallel fields and functional principles.

Contemporary schools of psychology. Among the numerous major and minor trends, the following stand out most clearly at the beginning of the twentieth century: *functionalism* (Dewey, Angell, Carr) and *behaviorism* (Watson) as the major American movements, with distinct roots in England (Darwin) and Russia (Pavlov, Bekhterev), respectively; and *Gestalt psychology* (configurationism; Wertheimer, Köhler, Koffka) and *psychoanalysis* (Freud), originally in Continental Europe, but now likewise chiefly represented in America, and thus contributing to the present day convergence of all schools into a more solidified common enterprise.

All these schools have been described as revolts against the ruling psychological school of the nineteenth century, *structuralism* (Wundt, Titchener), some of them objecting primarily against its subjectivism ("introspectionism"), others against its bit-by-bit approach as represented primarily by such "atomistic" concepts as sensation and association.

The chief aim of behaviorism is to establish a psychology exclusively on the basis of "objective"—external or physiological—observation undertaken in the manner of the physicist. Thus psychology would be freed from the uncertainties of introspective observation, or sub-

jective, "private" experience, which was the traditional method of psychology up to the end of the nineteenth century. A sizable number of more specific concepts or theories, such as those of the conditioned reflex, of the preponderance of environment and learning over heredity and maturation, etc., are more or less incidental, yet important characteristics of behaviorism.

The chief aim of Gestalt psychology—something anticipated by structuralism's major nineteenth century rivals, *act-psychology* (Brentano) and the psychology of William James—is to expand the scope of investigation, especially also of introspection, so as to embrace the meaningful units of experience ("phenomenology") or of behavior in their entirety, so that getting lost in insignificant detail and losing sight of the dynamic "field" context may be avoided.

At present there is a trend to weld these two basic tendencies in modern psychological development, the one toward objectivity and the other toward an adequate level of complexity, into a unified, new psychology. Conceptually most articulate among the many manifestations of such a convergence is *molar behaviorism* (Tolman) which endeavors to avoid the "molecular" inclinations of classical behaviorism as well as the lingering preoccupation with introspection of the gestaltists, incorporating at the same time features of functionalism.

Whereas both behaviorism and Gestalt psychology are in the "academic," experimental-theoretical tradition, functionalism and psychoanalysis stress problems of adjustment and thus try to encompass close-to-life features of behavior and their practical implications. The former specifies primarily in the tradition of evolutionary utilitarianism and expands in the direction of applied and comparative psychology, whereas the latter is in close touch with the outlook of psychotherapy.

In an effort to systematically classify theories and schools, the following three categories will best serve as guiding aspects: (A) their clarity as given by the degree of "formalization," (B) their frame of reference in terms of concentration upon variables in certain areas, or "regions," of observation and/or of inference, and (C) their "level of complexity" and its adequacy or inadequacy in the general framework of psychology.

(A) *Explicitness of theorizing. Intersubjectivity and Formalization.* The standards of "objectivity" for direct observation have repeatedly been stated to consist in "intersubjectivity," "lack of ambiguity," etc., and are best exemplified by the operation of pointer-reading and other cases of observation of spatio-temporal point coincidences. Similarly, in theory construction it seems to be possible to work with a system of symbols, or a "language," which is completely clear, i.e., which for all persons concerned, and for each person at different times, leads to identical results once the premises have been unambiguously stated and accepted. In such a case, one may speak of the "public" character, or the inter- and intrapersonal univocality, of construction and communication. The content of theorizing may be brought into the open and made precise to various degrees. The following major instances may be distinguished.

(1) Highest internal consistency of the kind described is achieved through the use of mathematics or, to an even greater extent, of symbolic logic. In this case one may speak of *formalized theorizing*. The farthest advance in this direction so far is Hull's "hypothetico-deductive" theory of rote learning in which the classical schema of association by spatial or temporal contiguity—to which the behavioristic schema of conditioning is conceptually related—is used to establish a system of postulates and derived theorems in the fashion of axiomatic geometry, to be checked against reality by experiments and revised if necessary.

Contrary to widespread belief, quantification is not an essential requirement in the establishment of utmost rigor in the above defined sense. In consequence, along with symbolic logic, such other purely relational, non-metric branches of mathematics as topology have also been used in the formalization of psychology, primarily by Lewin. Existing vaguenesses in topological psychology are mainly due to the insufficiency of the rules for the reality testing of hypotheses or predictions rather than weaknesses in the texture of the theory itself.—In statistics, an example of a non-metric yet mathematical procedure is ranking.

On the other hand, the frequently encountered merely programmatic employment of mathematical symbolism, such as in expressing, say, performance as a "function" of both stimu-

lus and motivation— $P \approx f(S, M)$ —will give only the external semblance of formalization unless the concepts entering the statement have been rigorously defined. And it will, aside from this, remain without much value unless the functional relationship has been stated with some degree of specificity.

(2) In a second, somewhat less rigorous, case, to be called *technical verbalization*, either more or less artificial terms, such as conditioning, are introduced, or common terms are vested with a new meaning by more or less arbitrary redefinition. The major emphasis is in this case usually on the definition of concepts, whereas theory construction and derivations are mostly of shorter breath than in formalized theorizing. Definitions themselves are often in terms of common language elucidation (as is, by the way, often enough the case with such so called "undefined concepts" as, e.g., "syllable exposure," "reaction," "stimulus trace" in Hull's formalized theorizing). Yet, a great deal of precision may be obtained by this technique especially when the terms are taken from the "thing language" (Carnap). There seems less danger of losing sight of meaningful content in the process of theorizing, such as often seems to accompany exalted rigor.

Examples from physics of technical redefinition are the intramural usage of "work," "clock," etc. In psychology, technical verbalization can be found at its best in molar behaviorism, especially in such fundamental instances as Tolman's "operational redefinition" of "purposive behavior" as "persistence through trial and error, and docility, relative to some end." As in the case of the concept of "work" in physics, the psychological concept of purposiveness is thus stripped of its introspectionistic and finalistic (vitalistic) connotations. At the same time a descriptive criterion is given for the testing or verification of any statement made about the presence or absence of purpose in the new, behavioristic, sense, in any instance involved. Furthermore, the fundamental principle of "vicarious functioning" is incorporated into one of the most basic, if not the most basic, notions in psychology. (This principle, by the way, has also been introduced by Hull in his earlier work on the "habit-family-hierarchy" but fell into oblivion after he turned to the more molecular enterprise of formalization.)

Yet, as in such common instances of technical

verbalization as law making by legislative bodies, there is seldom enough precision to render interpretation unnecessary. One of the few notable possible exceptions to this is Krechevsky's behavioristic redefinition, so far primarily applied to animals, of a "hypothesis" as a sequence of choices that is different from a chance sequence. Statistical criteria of significance might be applied to ascertain such a difference. Furthermore, there are few even among those introducing a redefinition who are able to keep the new technical meaning constantly in mind without slipping back into other technical or colloquial meanings of the term. (The use of subscripts to designate technical usages of terms has sometimes been suggested but so far seldom been carried through consistently in conventional write-ups.)

On the other hand, the hidden connotations and the accumulated apperceptive mass of terms loaded with tradition may often establish ties of meaning that will in the end greatly stimulate thought over and above the purely technical machinery to which proceedings otherwise might become limited. Although more mature disciplines may be able to afford to renounce such intuitive sources of progress, psychology in its present stage, with but few of its inherent problems explicitly stated, may do better not to dispense with this important life line. Thus for the sake of historical continuity operational redefinition of traditionally mentalistic terms may often be preferable to the coining of altogether artificial terms.

(3) The use of terms directly borrowed without redefinition from the vocabulary of every day life, to be termed *colloquial verbalization*, plays a decreasing role in modern psychological thought. Not long ago, however, a technique often employed in philosophy, that of attempting to "clarify" (rather than redefine) the meaning of a common term has been widely employed in introspectionism, e.g., in deciding whether sensations were "intentional"—i.e., pointing to an object outside themselves—or merely static contents of the mind, whether "orange" was a composite or a simple sensation, what was "immediately given" in experience and what was "mediate," whether or not there was such a process as "imageless thought," etc. Intuitions concerning the essence of language, of insight, or of a rejected minority group, fall in the same category.

Excursion on *level of abstraction*.—An aspect of special interest in this context is the development of what may be called the level of abstraction of concepts employed in psychological theorizing. The issue may be exemplified in the history of physics by the shift of the theory of the elements from concrete substances of daily observation, such as water or fire, to the highly abstract, often hardly visualizable constructs of electrons or wave fields. With the usual lag of many hundreds or even thousands of years, psychological theories have labored along the same path. For example, the "faculties" underlying the "phrenology" of Gall more than a hundred years ago are nothing but hypostasized daily activities, such as hope, speech, calculation, or imitation. In neo-facultative modern factor analysis, as developed especially by Spearman and Thurstone, the factors are the end product of a fully formalized system of derivation from test results and their statistical correlations. These factors emerge as purely mathematical constructs, and it is often very difficult to "name" them, i.e., to relate them to directly observable activities or even abstract features of such activities.

The theory of psychoanalysis which deals with the subject of motivation, a topic even more complex and subtle than that of physiognomics or intellectual abilities directly subsumable under the "reality-principle," has just recently started on this road of emancipation from the concrete. In its beginnings at the end of the last century, first one of the major of the directly experienced as well as outwardly manifested instincts, sex, was assigned a basic role by its founder, Freud. When Adler substituted the drive for mastery and social prestige as an alternative basis for reduction of a wide variety of observed strivings (including certain aspects of sex), it seemed like a revival of the water vs. fire alternative in ancient Greek natural philosophy. Very soon, however, it was made clear that the term "sex" was to be used in a redefined, broadened sense whereby the term "genital" was to take over the narrower function of what was colloquially called "sexual." The concept of "libido," especially emphasized by Jung, and designating a generalized vital urge, is an example of an artificially imposed term that at the same time led further away into abstractness. (In spite of such and other important differences, the schools of

Adler, of Jung, and of others differ primarily in content or technique rather than in basic theoretical texture from that of Freud and are therefore not especially considered in the present article.) It seems quite likely that in the future all concrete concepts used in preliminary theorizing on personality dynamics will give way to truly formalized constructs in the fashion of modern factor analysis. It may be expected that in the course of such a development many of the misunderstandings and endless controversies, as well as a good deal of the emotional resistance that so often arises against revolutionary statements made in terms of the common language vocabulary, will be mellowed and will eventually disappear. Needless to say that observational exactitude and statistical caution are apt to increase in parallel with the adoption of objective criteria in theorizing and a formalized set of concepts and assumptions.

(4) This side remark on level of abstraction leads us back from the primary emphasis on concepts characteristic of the various stages of informal verbalization to problems of the assertive content of theorizing. Due to the flexibility of the meaning of common terms, hidden assumptions or prejudices are apt to slip in unnoticed. In this case we have *unverbalized, implicit, theorizing*. In the development of psychology accusations of the presence of such "tacit presuppositions" play quite a prominent role in the struggle of new against older schools. Probably the best known instance is that of the "constancy hypothesis" which, according to Gestalt psychology, is tacitly inherent in many of the policies or specific assumptions of structuralism. According to this supposed hypothesis each isolated stimulus element impinging upon the sensory surface of an organism will—at least within each specific sense department—at first elicit an effect in consciousness that is univocally correlated to the character of the stimulus, e.g., a large retinal image the impression of largeness in strict proportion to the size of the area stimulated.

Inadequacy in the treatment of the pre-conscious, physiological interaction and organization of the perceptual field, such as of the tendency towards "good" figure, or of the perceptual thing-constancies—establishing correctness of judgment about, say, object size regardless of distance rather than about the size of the peripheral retinal projection—has been held

against the constancy hypothesis. It is being pointed out that its roots lie in the confusion of the actually observed "phenomenal" experience with the mosaic-like "functional" anatomy of the peripheral sensorium, leading to a false molecularism in introspective as well as eventually also in functional psychology. If all this had been made explicit, it is said, such an assumption would never have been made in earnest. Implicit hypotheses thus apparently may be much more harmful than explicit ones, quite aside from the element of irrational or wishful thinking that may enter into them.

(B) *Regional reference.* It seems that implicit theorizing has its best chance whenever explicit theorizing is programmatically discouraged. The best example is early behaviorism with its overt hostility to theory, rationalized as a wish to limit psychology to "fact" and thus to avoid the discord contained in traditional informal, speculative, "medieval" theorizing. Not only has this attitude been very short lived, giving way to elaborate formalized theorizing, but—what is more—an analysis of the research policies of classical behaviorism reveals the presence of an unusual number of unverbalized biases, which make a good case for Goethe's statement that "any fact is in itself theory." One of the most important of the prejudices inherent in behaviorism is its *peripheralism*, which may be rationally reconstructed as the implicit belief that what is important in the life and behavior of an organism can be found and identified at its surface—apparently because of the fact that that is the portion which is most conveniently observable—thus rendering theoretical construction of what Tolman has called "intervening variables" unnecessary. A long series of frustrations marks Watson's search for "the" organ of learning, first among the organs of the sensory, then of the motor periphery. Only the hard way, by experiment, and in the course of the resulting reorientation toward a molar behaviorism by Tolman and by Lashley is the "generality" of animal learning, the vicarious functioning of sensory as well as of motor cues or departments, and with it the central basis of orientation and the prime importance of the brain, being made clear.

By the same token, and in line with the spirit of functionalism, the actually-achieved environmental end-results of a behavioral unit (e.g., the actual reaching of food) becomes one of

the most important focal regions of observation. Result-variables of this kind are a special case of what recently is sometimes called a *distal* variable (Heider, Brunswick). It may then be said that the peripheral, sensory-motor unit of the glandular or muscular reflex is in both Tolman and Hull (in the latter only in his pre-formalization phase) being overshadowed by a central-distal outlook.

From the concept of implicit theorizing it is only a short step to a discussion of such major movements in psychology which, in spite of the employment of often very high powered theoretical procedures, are characterized by the absence of that aggressive or propagandistic superstructure which would make them schools in the traditional sense of the word. Yet, by virtue of a relocation of the focal regions of interest, as well as of other changes in basic research policies, some of them are as revolutionary as their more vocal competitors, or even more so; such movements may thus well be called "implicit schools." In line with a general reluctance to indulge in open theorizing—a kind of intellectual puritanism—implicit schools are found most prominently in America. The functionalism of the turn of the century has often been said not to be a system in the customary sense; yet this is due not so much to a lack of explicitness but rather to the fact that functionalism embraces a variety of heterogeneous movements which had joined forces against structuralism. Truly implicit schools have not even gone to the trouble of finding a label for themselves which would characterize them as an "ism." Identifiable merely by the names of their most outstanding representatives, the following three stand out within academic psychology: Lashley, Thurstone, Murray. Along with such explicit theorists as Tolman, Hull, or Lewin, they have probably exerted the strongest influence in the current reorganization of actual psychological research policies, at least in America which is at present the center of psychological work.

It is significant of the *convergent trends in present day psychology* that, with all of the existing differences, the work of the leading psychologists just mentioned, possibly with partial reservations in the case of Hull and of Lewin, can be subsumed under the above formula of a shift from peripheral to a more *functionalistic, central-distal* emphasis.

In the case of Lashley, the emphasis on the central region which Tolman introduces by inferring "intervening variables" such as "purposes," "hypotheses," etc., in new, operationally redefined versions, is found in such observational directness as to be acceptable without ambivalence even to the traditional behaviorist. The only direct approach to the central region is the physiological. It is through experimental brain-lesions in rats in the case of Lashley. This approach is radically different from the sensory technology, or the sensory-motor reflexology, of the structuralists, or of the early behaviorists, respectively. The genuinely psychological character of this work is given by the fact that, just as in the case of Tolman, the central variables—such as extent of cortical lesion—are linked to, or correlated with, the reaching of a certain characteristic end state, such as the arrival in the food compartment of a complex maze.

Lewin's foothold in the region of behavioral results is somewhat doubtful as far as his theoretical system is concerned; all his real emphasis centers on inferences concerning, and the intrinsic lawfulness of, the central region, *per se*. The Lewinian "life space," which refers to the internal setting of the stage for action after perception has taken place, is conceived as a dynamic "field" rather than a conscious reality. This is an important step toward objectivism, although it has been pointed out that much of Lewin's rather casual technique of inferring the life space may in fact be "phenomenological" in the introspectionistic sense. As is conscious experience, the life space, being segmented into macroscopic units, is ideally describable in terms of a non-metric topology (see above) and Lewin is to be credited with the fact that he is the first and so far the only major psychologist to attempt the use of this happily non-quantitative yet mathematical instrument. Given the limitation of scope inherent in this comparative encapsulation into the central layer—which has definitely to be considered a molecular feature—it may be relatively simple for Lewin to develop psychological laws, especially if supported by a somewhat unscrutinized side glance at overt behavior as a testing ground for the predictions made.

Whereas Lewin, with his primary emphasis on central field dynamics, reveals his direct descent from Gestalt psychology most

clearly, both Lashley and Tolman may be looked upon as those most evenly balancing behaviorism and Gestalt psychology into a new synthesis of these two major schools. Likewise, it is in Tolman and Lashley that the functionalistic component, represented by utilitarian result-emphasis, becomes most prominent. Hull's espousal of intervening variables and of the concept of molar behavior may help to illustrate his tendencies toward, and emphasis on, central processes.

Thurstone's functionalistic leanings on behavioral results are revealed by his start from test scores. In counterdistinction to most other testers, however, he does not consider the mathematical evaluation of such results in terms of correlation or factor analysis merely as a more economical description within the distal layer. By ostentatiously adopting the much scorned tradition-loaded term "faculty" as an alternate to the neutral term "factor," he clearly puts the emphasis on the central layer of abilities and dispositions. And by the strict formalization of the rules of inference of the central factors from the distal test-scores he sets an unparalleled example of exactitude in the theoretical establishment of intervening variables. For this reason, as well as probably for the minimum display of an explicit school-superstructure, Thurstone shares with Lashley the probably least ambivalent acceptance of his particular style of work in spite of the fact that Thurstone freely indulges in theorizing of an inferential kind.

Whereas up to this point the synthesis was of behaviorism with functionalism or with Gestalt psychology or both, Murray may be considered as the academic psychologist who has gone farthest toward an integration with psychoanalysis. The emphasis on the central which he shares with all the other contemporaries listed, takes in him the form of an emphasis on "needs." As in psychoanalysis, the center of gravity is thus placed on forces of motivation assumed to be relatively stable whereas in Tolman and Lewin it is more the fluid, short-range changes of motivation that absorb most of the interest, and in Thurstone it is primarily the cognitive rather than the motivational side of the relatively permanent pattern of dispositions that absorbs the bulk of attention. The shift from the peripheral to the distal variables is reflected in Murray's emphasis on the "effects"

of behavior rather than the "actones" which constitute behavior when viewed as it issues from an organism. As is psychoanalysis, Murray's system of needs and its environmental conditions as well as consequences is one of the least formalized and thus most severely criticized. As does psychoanalysis, however, it probably contains the seeds for a system more comprehensive in scope than are those based more exclusively on the academic tradition, exemplifying once more the inverse relationship that exists—at least during the adolescent period of a science—between methodological perfection, on the one hand, and adequate complexity, on the other.

Generally, the most fundamental regional difference between academic psychology and psychoanalysis is the former's preoccupation with "geographic" environmental relationships, the well-known stimulus-response schema, whether the stimulus be "proximal" (peripheral) or "distal" (including the social). In contrast to this, psychoanalysis endeavors primarily to discover relationships of present motivation to certain focal regions along the "historical" axis, mostly the remote past, including especially early childhood. Recent academic emphasis on motivation as an experimental variable (Tolman and others), on "operant" (spontaneous) as contrasted with "respondent" behavior (Skinner) will in the end help to close a gap that should be recognized as one of divergent interest in wide open spaces rather than as one of conflicting views on a crowded common battleground of research.

(C) *Level of complexity and closeness to fact.* After discussing primarily some of the formal aspects of theorizing, such as explicitness, the aspect of the material content of a theory was brought into the picture so far primarily under the heading of differences in regional emphasis among the various schools. Other aspects of content are primarily those of scope, or level of complexity (molar vs. molecular outlook) and certain allied methodological problems (such as primarily experiment and "law" vs. statistics). These aspects can conveniently be called to attention in close connection with still another formal aspect of theorizing, namely that of the relationship of theory to the factual reality of observation. This shall be done here under the heading of "close-

ness to fact" of a theory. The following major instances will be distinguished: (1) surface theories, maintaining the observational level of complexity, and (2) dynamic (explanatory) theories of both the (a) subordinate, mediational and (b) the superordinate, functional type, characterizing a more macroscopic and a more microscopic level than that of the original sequence or co-existence of observations.

Some theories are close to what is customarily called a pure "description" of fact. The simplest way of describing facts is by *enumeration*. In this case, however, facts remain unrelated to one another and no predictions can thus be derived from them. Therefore, this approach is often considered to be outside of what is usually understood to constitute "science"; and it does not contain any element of theory, although a formalized "language" may be necessary to establish it.

(1) Theory begins with synopsis. But it is only in idealized cases, exemplified, say, in geometry, that description can truly be said not to go beyond the fact. A good illustration is the description of a circle or any other line by an equation, as is done in analytic geometry, instead of by an enumeration of all of its points. But whereas in geometry the number of points is infinite, in any empirical science only a finite and often very limited number of points is available. Synoptic description in this case becomes the fitting of an idealized continuum of points to a discontinuous series of points. In accepting the fitted curve as an alternative description one thus already transgresses the facts available; the points "interpolated" between the existing data, as well as especially those "extrapolated" beyond the ends of the observed series of points, contain an element of prediction, stated in terms of what amounts to a "law," which definitely oversteps the boundaries of a purely synoptic alternative to simple enumeration. Yet, when compared to other instances of theorizing, curve fitting stands out as singularly non-interpretative and lacking in dynamic implications, unless of course the character of the curve is taken as a starting point for further considerations, comparisons and reductions. Thus "phenotypical approach," or "phenomenological theory" (the term here not in its introspectionistic meaning), "empirical theory," "descriptive theory," or *surface theory* would

seem to be appropriate labels for synoptic description.

Most outstanding examples of curve fitting in psychology can be found in the experimental psychology of learning and of forgetting (with the logarithmic curve as a favorite), as well as in other more strictly developmental fields. The most comprehensive approach of this kind was recently undertaken by Woodrow in an attempt to find a "generalized quantitative law" for a wide variety of fields in psychology including learning, psychophysics (as an alternative to the earliest genuinely psychological quantitative law formulated, the Weber-Fechner law), the development of intelligence, and others. In combining two hypothetical factors, one for the ceiling inherent in all human performance, the other representing what might crudely be labeled sensitivity, Woodrow went somewhat beyond a mere synopsis, in the direction of underlying dynamics, but he himself regards his attempt as a surface theory. Being an exponential function with a large number of parameters which vary from application to application—in contradistinction to the "universal" physical constants, such as the speed of light, which remain the same in a wide variety of contexts—Woodrow's formula can be fitted to an extremely wide range of curve shapes, thus reducing the value of synopsis which would seem to lie in comparative specificity. There can be no doubt, however, that this kind of theorizing has a place and a future in psychology.

Another frequently used instance of synoptic description is the correlation coefficient and related measures of concomitant variation of variables. As are the mathematical functions mentioned above, correlation coefficients are abbreviated, comprehensive—although not complete—descriptions of sets of points in space, in this case determined by the frequencies over the cells of a two-dimensional scatter diagram. Contrary to frequent, often tacit misuses in practice, a correlation coefficient does not indicate direct causal relatedness of the two variables in question and is therefore just another instance of a theoretical construct to be subsumed under surface theorizing.

(2) Whenever the genotypical, conditional-genetic approach involving generalized "nomothetic" (i.e., law-asserting) statements about cause and effect is involved one may speak of

dynamic theories. More broadly, the term may also be applied to assumptions about individual, "idiographic," cause-and-effect sequences without reference to lawfulness. Although most textbooks explicitly warn against confounding observed correlation with causation, few rules are given for the methodical determination of cause and effect sequences. There can be no doubt, however, that in the end all such statements are based upon the observation or application of some kind of empirical correlation. Two major ways seem to be open: (a) by the use of statistics, gathering and combining observed correlations with only imperfect control over remaining relevant conditions, along pathways prepared by partial and multiple correlation or related techniques; none of these techniques have, however, yet been developed to an inclusiveness which would guarantee causal analysis of a foolproof nature. Or (b) by the use of the classical type of experiment, rigidly controlling all relevant conditions and observing concomitant variations of the one (or few) remaining ones. Most of the laws formulated in physics, and some stated regularities in psychology have been established in this latter fashion. In the field of personality and individual differences, however, only limited controls are possible and statistical methods, including the above mentioned factor analysis, have been more successful. Many statements of causation in this and other fields have been left to informal or even unverbalized theorizing often labelled "intuition," "understanding," and the like, which upon being made explicit would most likely reveal their character as a statistical theory, though most likely lacking in sufficient scrutiny with respect to sampling, separation of issues, etc.

There is a close relationship between dynamic theories and what is customarily called *explanation* of a fact or an observed regularity. To remove any semblance of a fundamental cleavage, explanation has sometimes been called "added description," in the typical case through reference to generalized evidence stated in the form of a sometimes more, sometimes less rigorously established law or regularity. There are two major usages of the term "explanation" in psychology.

(a) Most specifically, it is applied to a tracing of a chain of cause and effect through many, and in the ideal case through all, the

intermediate stages that lie between the originally observed coexistence or succession of facts. Quite frequently observation of such intermediate stages is impossible and systematic principles of a lower level of complexity, but usually of higher generality, often called micro-laws, are called upon to substitute for historic-geographic observation on the spot.

In colloquial terms, such tracings attempt an answer to the question "How does it work?" and the assumptions adopted, idiographic or nomothetic, may therefore be called "how-theories," "technological theories," "micro-theories" or, preferably, *mediation theories*.

Generalized mediation theories play an outstanding role in psychology, and can be found in their purest form in the theories of vision and audition developed ever since the middle of the last century by Helmholtz and others. They are based on observations of gross correlation between such stimulus variables as wave length of light or sound, on the one hand, and of psychological response qualities such as sensations of color and tone and their attributes, such as hues, subjective pitch and loudness, etc., on the other. Unresolved alternatives, such as those existing among the resonance theory, the telephone theory, or the volley theory of the functioning of the ear and the auditory nerve, occupy the interest of psychologists up to the present. Their counterparts in the field of vision have, without being completely settled, already faded from the attention of psychologists into the domain of a more molecular discipline, physiology. Many other mediation problems may ultimately become relegated to such more "fundamental" sciences.

Mediation theories of much broader scope have recently been developed to explain features of behavior which themselves span a considerably wider range than those existing between proximal stimuli and peripheral excitations or central sensations. The most outstanding example is Hull's theory of behavior, a sequel to his work in formalized theorizing mentioned earlier in this report. Hull tries to fill the gap between the geographical stimulus-environment existing at a certain moment, on the one hand, and the accomplished behavior act, on the other, with a chain of *inferred* links, combining the Pavlovian schema of conditioning with the Thorndikean principle of reinforcement through the law of effect (satis-

faction of drive). This schema, emphasizing past experience (or past behavior) as has English associationism and later structuralism, is, however, only one of two major alternatives. The opposite theory is one of internal field dynamics, more specifically, of the closure or completion of incomplete patterns—which include unsolved "problems" along with the originally studied incomplete geometrical patterns which perceptually tend to become "better," more regular, symmetrical, simple, in short, "prägnant"—through the intrinsic laws governing the interplay of forces within the "closed system" of the organism. Various forms of such a theory have been proposed by Gestalt psychology and related movements, such as the Würzburg school of Külpe, Bühler and Selz. The association and completion theories have in common that they are phrased in terms of intervening variables, and sometimes even in quasi-physiological terms, by the use of such "unobservables" as excitatory or inhibitory potential, brain field, etc., and only indirectly in terms of the environment. It is for this encapsulation within the organism that both of these theories have to be classified as *mediational*. (The same holds, by the way, for the highly mathematized theories of Rashevsky and his collaborators.)

There remains, however, an important difference that characterizes the association theory as more "molecular" in comparison with the completion theory. In the interpretation of the Gestaltists the association theory, being patterned after the model of the reflex arc, or of a telephone switchboard system, is a "machine theory," whereas the completion theory is dynamic in a more genuine sense of the word by its emphasis on free interaction of energy within large areas of the nervous system. The basic conception of "mass" functioning of the nervous system as developed by the modern behaviorist, Lashley, or by the biologist, Paul Weiss, is in accord with such a field interpretation. Under this aspect Lashley, along with Tolman, has to be classified as a molar behaviorist whereas Hull retains some characteristics of molecular behaviorism in spite of an attempt to introduce several specific molar features into his behavior theory, such as "stimulus patterning," "behavioral oscillation," etc.

(b) Given an observed macroscopic causal correlation of two variables, one may, as an

Theories about Theories and Research Policies in Psychology.—The above discussion leads us to the various arguments that can be found throughout the psychological literature in judging the value or adequacy of certain fundamental assumptions or basic policies adopted by individuals and schools in psychology. Some of these issues have been brought up before in this report, such as the problem of objectivity, formalization, or operational redefinition. Other theories about theories deal with genetic problems of the history of science.

An outstanding recent example is Lewin's distinction of Aristotelian and Galileian modes of thought in psychology, somewhat similar to Comte's distinction of the theological and metaphysical vs. the positive stage in the development of science in general. The Aristotelian mode of thought is taken as a representative of the older philosophical or speculative approach and is most characteristically manifested by a tendency toward the setting up of "dichotomies," i.e., of absolute rather than relative distinctions between opposites, such as mind and matter, learning and insight, mechanism and vitalism, nomothetic and idiographic disciplines, etc. Galileian modes, according to Lewin, lead to the transformation of such notions into truly scientific ones, the replacement of differences in kind by differences of degree, a general adoption of quantitative methods and a discovery and emphasis upon lawfulness. In consequence, theories should be, and are in practice, judged not only in terms of their direct merit, but also more indirectly, in terms of their genetic level which in a general way may allow us to anticipate their adequacy.

To the present reviewer, the discussion about the status of laws in psychology seems of particular importance. In fact, he is inclined to advocate the replacement of the classical experiment, with its emphasis upon the discovery of strict laws, by a more statistical procedure even in stimulus-response psychology as the only practicable way to establish an exact, yet molar objective psychology. Imperfect correlation or probability laws would then take the place of unequivocal laws, although the latter most likely "exist" and can be discovered at the expense of adequate complexity.

Another issue of similar, methodological nature is the relative weight to be assigned to the idiographic, case-descriptive, "clinical" approach

as contrasted with the nomothetic, more generally law-finding (which in this alternative would include the statistical). This is a reiteration, on a more advanced and formalized plane, of the old controversy as to whether psychology in its basic orientation is a natural science dealing with generalities, or a "cultural" science (*Geisteswissenschaft*) dealing with singularities, or at least with "individuals" that have to be intuitively "understood" in terms of some—possibly self-consistent, i.e., idiographically "lawful"—personal "styles of life" peculiar to them alone.

Theoretical issues of this type may appear to stand isolated at times, yet the answers given to them form the nucleus of the fundamental philosophies of science crystallized in the various psychological systems or schools.

BIBLIOGRAPHICAL NOTES

Only references to publications in, or translations into, English are included here. Sources for the most recent movements in academic psychology are given in somewhat greater detail, since they occupy the limelight of recent discussion and since only scant comprehensive treatments or adequate up to date bibliographical selections have appeared after the early thirties. An effort has been made to select in each case the most concise presentations available, among them quite often presidential addresses of the American Psychological Association, so that the reader may be enabled to make the best use of his time and energy in his endeavor to obtain a full view of the issues involved in modern psychological theorizing.

(1) *Original sources on schools and movements.*—The two major historical forms of nineteenth century introspectionistic psychology are most outstandingly represented in American psychological literature by Wundt's pupil, E. B. Titchener, in his posthumously published presentation and belated defense of structuralism, *Systematic Psychology, Prolegomena* (Macmillan, 1929), and by W. James, in his chronologically much earlier but in spirit more modern *Principles of Psychology* (2 vols., Holt, 1890) which shows some common elements with Brentano's act-psychology but in certain ways also foreshadows most of the later "crisis" schools, including American functionalism, behaviorism, Gestalt psychology, and even psychoanalysis.

These major movements are in their original form most clearly represented in J. R. Angell's presidential address, "The province of functional psychology" (*Psychol. Review* 1907, 14), in J. B. Watson's third and latest book, *Behaviorism* (Norton, 1924), K. Koffka's *Principles of Gestalt Psychology* (Harcourt-Brace, 1935), and S. Freud's *Introductory*

Lectures on Psychoanalysis (Allen & Unwin, 1922, originally 1917), the latter to be augmented by such indexed and glossaried *General Selections* from his works as the one edited by J. Rickman (Hogarth Press, 1937).

The formalized, physiological-behavioristic theorizing centering about learning problems reaches a climax in two books by C. L. Hull (the first in collaboration with several other authors), *Mathematico-Deductive Theory of Rote Learning* (Yale Univ. Press, 1940), and *Principles of Behavior* (Appleton-Century, 1943). Especially the latter has, in the years immediately following its publication, elicited an unprecedented amount of critical reviewing, discussion and counter-discussion, such as in the *Psychol. Bulletin* (Koch, Ritchie; on math-ded. theory: Hilgard and others), the *Journ. of Genetic Psychol.* (Leeper, Welch), the *Amer. Journ. of Psychol.* (Skinner).

More important from the standpoint of the development of a molar approach is some of the last of Hull's writing of his period preceding formalization, especially three articles on "The concept of the habit-family hierarchy" and related schemata (*Psychol. Review*, 1934-35, 41, 42). Less well known among psychologists, but no less important in the field of formalized quasi-physiological theorizing in psychology at large, and gradually working up to such complex topics as esthetic appreciation of forms, Gestalt problems, the perceptual thing-constancies, etc., are N. Rashevsky's *Mathematical Biophysics* and *Advances and Applications of Math. Biology* (Univ. of Chicago Press, 1938 and 1940, resp.), followed by A. S. Householder and H. D. Landahl, *Math. Biophysics of the Central Nervous System* (Math. Bioph. Monogr., No. 1, 1941), and largely based on, and augmented by, numerous papers in *Bulletin of Math. Biophysics* (beginning 1939). A less technical type of formalization of learning theory is attempted in B. F. Skinner, *The Behavior of Organisms* (Appleton-Century, 1938). For a general discussion of learning theories see E. R. Hilgard and D. G. Marquis, *Conditioning and Learning* (Appleton-Century, 1940).

Molar behaviorism of a non-vitalistic, operational kind representing a convergence with both functionalism and Gestalt psychology is first conceived by E. C. Tolman in his *Purposive Behavior in Animals and Men* (Appleton-Century, 1932), as well as in "Psychology vs. immediate experience" (*Philos. of Science*, 1935, 2) and a series of articles, many of them in the *Psychol. Review*, including one in collaboration with E. Brunswik on "The organism and the causal texture of the environment" (1935, 42), and the presidential address. "The determiners of behavior at a choice point" (1938, 45). One of the most outstanding operational redefinitions of an originally introspectionistic concept may be found in I. Krechevsky, "Hypotheses in Rats" (*Psychol. Review*, 1932, 39). An excellent presentation of the experimental evidence forcing the shift from Watson's peripheral to Tolman's central behaviorism, together with illustrations of the methodological changes involved, is given in R. S. Woodworth, *Experimental Psychology* (Holt, 1938, first half of Chapter 6). Still closer to Gestalt

psychology than Tolman is K. Lewin, *Dynamic Theory of Personality*, and *Principles of Topological Psychology* (McGraw-Hill, 1935 and 1936, resp.), continued in his still more technical *Conceptual Repres. and Meas. of Psychol. Forces* (Contrib. to Psychol. Theory, No. 4, 1938), and in "Formalization and progress in psychology" (Univ. of Iowa Stud. in Child Welfare, 1940, 16-3). Going beyond Gestalt psychology in the direction of an objective functionalism as does molar behaviorism, but centering about the perceptual thing-constancies rather than about the means-end problems which constitute their mirror image on the overt behavioral side, is E. Brunswik, in a summary of his book whose title is best translated as "Psychology in Terms of Objects" (1934): "Psychology as a science of objective relations" (*Philos. of Science*, 1937, 4; some serious errata corr. 1938, 5).

The best source for H. E. Murray's synthesis of certain elements of modern psychology and of psychoanalysis are the first two chapters of his *Explorations in Personality* (in collaboration with numerous other authors of the Harvard Psychological Clinic; Oxford Univ. Press, 1938). The ambiguous character of the need-to-effect relationship involved is stressed in E. Frenkel-Brunswik, *Motivation and Behavior* (Genetic Psychol. Monographs, 1942).

Only scant theoretical utterances are available in the case of such "implicit" school-leaders as Lashley and Thurstone. The former's "Basic neural mechanisms in behavior" (*Psychol. Review*, 1930, 37), and the latter's non-technical "The vectors of mind" (*Psychol. Review*, 1934, 41)—both presidential addresses—, as well as Thurstone's defense, against Anastasi and others, of his factors as the operational revival of the old "faculties" in "Shifty and mathematical components" (both authors in *Psychol. Bulletin* 1938, 35; see also 1940, 37), may be consulted to advantage.

(II) *Texts on schools, and other comprehensive treatments*.—The period up to the close of the era of divergent schools of psychology, i.e., roughly up to 1930, has found its terminal expression in a number of comprehensive books. Among these probably the most widely used is E. Heidebreder, *Seven Psychologies* (Appleton-Century, 1933), a clear and well proportioned presentation of the major systems on a relatively elementary level, and with an adequate selection of references to original sources up to that period which may serve as a first guide to those interested in the semi-historical literature on systems of psychology. Of similar intent but of somewhat lesser inclusiveness is R. S. Woodworth, *Contemporary Schools of Psychology* (Ronald Press, 1931). With a historical slant, and organized more about fields than schools proper, is G. Murphy, *Historical Introduction to Modern Psychology* (Harcourt-Brace, 3rd ed., 1932), with an appendix by H. Klüver on such exclusively continental movements as "intuitionism." For similar reasons, R. Müller-Freienfels' somewhat unwieldy *Evolution of Modern Psychology* (Yale Univ. Press, 1935), may also be recommended, although with reservations. First hand summaries of a considerable number of schools by their originators or by close collaborators

were assembled by C. Murchison in *Psychologies of 1925*, and of 1930 (Clark Univ. Press), among many others of such sometimes otherwise not easily accessible but important authors or movements as Sander's brand of configurationism (the Leipzig group), Russian "objective psychology" and "reflexology" in both the Pavlov and the Bekhterev versions, and Janet's and Adler's sub-varieties of psychoanalysis.

Comprehensive presentations of the developments in psychological theorizing since the early thirties are at this writing available only in the form of short articles of necessarily limited usefulness, and even these are few and far between. Almost without exception, these papers also reflect the current general trend toward a higher level of abstraction in the presentation or discussion of schools or theoretical issues. E. Brunswik, "The conceptual focus of some psychological systems" (first publ. 1939, reprinted in *Twentieth Century Psychology*, ed. by P. L. Harriman, Philos. Library, 1946) uses a considerably oversimplified, schematic presentation of the various schools in terms of regions and patterns of their research emphasis. A fundamentally similar purpose, but even more stressing systematic issues rather than schools, underlies the penetrating study by F. Heider, "Environmental determinants in psychological theories" (*Psychol. Review*, 1939, 46). The merits of J. R. Kantor, "Current trends in psychological theory" (*Psychol. Bulletin*, 1941, 38), are somewhat obscured by the author's going off the main line of current discussions. A unique survey of the changing points of view implicit in the psychological research since the closing decades of the nineteenth century is given in G. W. Allport's presidential address, "The psychologist's frame of reference" (*Psychol. Bulletin*, 1940, 37). This analysis based on careful study of the content of articles in the leading psychological periodicals may well anticipate a future development toward an objectified and statistical treatment of the history and trend of psychological ideas.

(III) *Systematic discussion.*—The recent emphasis on discussion centering about fundamental problems and basic methodological issues inherent in the founding of schools, rather than about these schools as the unifying centers themselves, is represented in such books as C. C. Pratt, *The Logic of Modern Psychology* (Macmillan, 1939), and C. R. Griffith, *Principles of Systematic Psychology* (Univ. of Illinois Press, 1943). Both these ambitious undertakings fall, however, somewhat short of their mark. The latter contains the most nearly complete list of references in theoretical psychology, at least as far as the recent American literature appearing as books or in the routine theoretical periodicals, including the philosophy of science relevant to psychology, is concerned, giving more than 1500 titles. E. G. Boring's most recent historical treatise *Sensation and Perception in the History of Exp. Psychology* (Appleton-Century, 1942), presents material or discussion relevant to systematic problems and schools of psychology (in Chapters 1, 2, 7, and 8).

In the periodical literature, the following two issues seem to emerge as rallying points in the modern type of methodological theorizing: (1) ob-

jectivity in its broadest sense, the problem of being "exact"—or "scientific"—in psychology, which is at the root of behaviorism and is most recently reflected by the discussion on operationism in psychology, and (2) the problem of keeping on an adequate level of complexity, i.e., sufficiently rich and close to life in context, scope, and content, "molar" rather than "molecular," as represented by the various programmatic trends inherent in Gestalt psychology, psychoanalysis, as well as in a good part of functionalism. Symposia have recently been devoted to each of these two basic issues.

(1) A "Symposium on Operationism" (*Psychol. Review*, 1945, 52 No. 5), with Boring, Bridgman, Feigl (shifting toward the problem of the level and generality of laws, and of explanation), Israel, Pratt and Skinner as contributors, climaxes a development of interest in "methodological positivism" that found its first comprehensive presentation in American psychological literature in S. S. Stevens's frequently quoted article on "Psychology and the science of science" (*Psychol. Bulletin*, 1939, 36) and has since achieved major proportions. It is closely related to the trends toward methodological integration of the physical with the biological and social sciences in terms of observation as well as of logical formalization advocated directly or indirectly by such contributors to the *Internat. Encyclopedia of Unified Science* (Univ. of Chicago Press, beginning 1938) as Carnap, Morris, Dewey, Russell, Woodger, Reichenbach, Brunswik and Ness. Among the numerous isolated articles on related problems we mention only two of the most outstanding and best known: G. Bergmann and K. W. Spence, "Operationism and theory in psychology" (*Psychol. Review*, 1941, 48), and the latter author's "The nature of theory construction in contemporary psychology" (*Psychol. Review*, 1944, 51).

(2) In a "Symposium on Psychology and Scientific Method" (University of Chicago, 1941; publ. in No. 3 of *Psychol. Review*, 1943, 50), Brunswik, Hull, and Lewin discuss what seems more recently to crystallize as the nucleus of the problem of adequate complexity, namely the formal criteria of behavior, the alternative of classical laws vs. statistical probability laws, and the status of the "intervening variables" as well as of the "field" concept in psychological theorizing. The classical desire to encompass psychological phenomena by one or a few fundamental laws climaxes in H. Woodrow's presidential address, "The problem of general quantitative laws in psychology" (*Psychol. Bulletin*, 1942, 39). The closely related more purely methodological alternative of classical "pure case" experiment vs. a more representative type of experiment in the study of stimulus-response correlations is answered in favor of the latter in E. Brunswik, *Distal Focusing of Perception* (Psychol. Monographs, No. 254, 1934). Indirect support for the probability conception of psychological research may be gained from such authors as the physicist, R. v. Mises, in his *Probability, Statistics and Truth* (Macmillan, 1939).

The relationship—methodological or otherwise—of academic psychology as a whole to psychoanalysis is discussed by both sides in a "Symposium on Psychoanalysis as Seen by Analyzed Psychologists" (in-

and the results of application to defectives were compared with their Binet scores. Agreement was generally close, but it was noted that, as subjects approached moron levels the discrepancies between the test verdicts tended to increase. However, where there were serious disagreements, reports from the manual arts instructors usually supported the Maze test scores rather than the Binet.

Early in 1914 the tentative scale was applied to a large group of deaf cases attending an institution school, and it was proved possible by its means to pick out those judged by teachers to be feeble-minded. All these defectives scored markedly below the pupils with normal mentality. After certain modifications were made, the tests were applied to a group of 120 subnormals. In 80 per cent of cases the Binet and Maze records were within one year of each other, but it was in the remaining 20 per cent with greater differences that the Maze test verdicts were of most significance. In some of these cases the Maze score proved decisive as regards differential diagnosis.

The same year the tests were first publicly described and results reported at a meeting of the British Association for the Advancement of Science, which held its 1914 sessions in Australia. In June, 1915, the tests were published simultaneously in the *American Journal of Psycho-Asthenics* (14) and the *British Journal of Experimental Pedagogy* (15). It is interesting to note that the tests have survived both media of publication.

The following year marked the first application of the tests to delinquents. A group of reformatory cases registered significantly lower performances than another group of less serious offenders resident at a boys' home. An interesting pioneer study was also undertaken at this time. Aboriginal children, mainly half castes, were examined at a mission school at Point McLeay, South Australia, and the results reported in *The Psychological Review* (16).

In 1916 there occurred an opportunity to test the standardization of the tests with normal children. The records of 190 of these were compared with the scores of 200 defectives who had been examined by the Goddard Revision. The same article reported results of testing 263 cases by Terman's Stanford Revision (17). Some results with delinquents and deaf children were also included in this publication. The correla-

tion coefficient for the mentally deficient group was .7, for 190 normal cases .69, and for 263 cases examined by the Terman revision .77. The group contained some defectives and a wide range of mental ages.

Encouraged by these results, the writer, with two assistants, embarked on what was then considered an extensive program of research. One thousand children attending rural and city schools were examined with Binet and Maze. This was one of the first studies which called attention to the differences on test responses exhibited by city and country children. Correlations at each age level were calculated, but as the range was artificially restricted these varied from .24 to .61 for boys and from .41 to .75 for girls. Some change was made in the test designs and the scale was reapplied to 1,255 cases. The results were published in 1920 (1). A similar investigation undertaken by Professor Cyril Burt in 1921 showed that with London school children the standardization of the Maze up to 14 years was reasonably correct (3). The same year marked the first study of the Maze test in a non-English-speaking country. The results of application of the test were the subject of a thesis presented by Dr. Carlos Miranda to the Faculty of Medicine in Lisbon.

At Vineland, New Jersey, where the writer took up his duties as director of research in 1919, the work of validating the tests was continued. The criterion was a number of industrial ratings of inmates of the Training School supplied by Mrs. C. E. Nash, educational director. Boys' ratings correlated .67 with the Maze, .62 with the Binet, .61 with a group of Army performance tests. Girls' ratings correlated .75 with the Maze, .66 with the Binet (18). Ross (29), in Scotland, also working with defectives, confirmed these findings as to the relation of industrial trainability to the Maze test. She found for defectives a correlation of .81, and with a mixed group of defectives and normals the Stanford-Binet correlated .69, the Maze .76, the criterion being teachers' ratings of pupils' handwork.

The devising of a measure of social adaptability, called "A Social Rating Scale for Defectives" (19), provided another criterion against which the validity of various mental tests could be compared. A number of studies were undertaken at Vineland, mostly by Dr. Marjorie Babcock. In the first, 38 males yielded very similar

correlations for the Binet, Maze, and Goddard Form Board with the social ratings. All were about .6, but when the Binet and Porteus were averaged the correlation with the criterion rose to .73. For 44 females the Binet correlated .69, the Goddard .63, and the Maze .75. The coefficient for the Binet-Porteus average was .79. When the cases were limited to those with mental ages above 8 years, the relation of the Goddard test to social adaptability was lowered significantly, proving that the Form Board was most valid at the lower mental levels where its verdict was needed least for diagnostic purposes.

In six other studies the Binet correlations with social adaptability were respectively .32, .82, .62, .46, .85 and .60, or an average for all studies of .61. For the Maze the coefficients were .7, .81, .64, .72, .78 and .67, or an average of .72. As a significant by-product of these investigations we may call attention to the variability of the coefficients, notwithstanding the fact that all groups were mental defectives, thus proving the importance of sampling. Differences in chronological and mental ages and industrial usefulness distinguished the various groups. Perhaps the most significant study was the last carried out, in which 100 fairly typical of the feeble-minded population were examined. The correlation of the Stanford Revision with the criterion was .6, whereas the Maze coefficient was .67. These results were reported in 1923 (20).

Miss Doris Dewey also made a similar investigation, the results of which were reported in a later monograph (21). She used a variety of tests and obtained the following correlations with the social criterion: Maze .77, Porteus Form and Assembling .72, Kohs Block Design .71, Pintner-Paterson .66, Stanford-Binet .62, Goddard Form Board .63, Knox Cube Imitation .12. This study served to indicate that some performance tests have a closer relation to social adaptability and therefore to mental diagnosis than the Binet. However, a combination of Binet and Maze mental ages correlated .82 with the criterion, suggesting rather forcibly the wisdom of using the two tests in a battery. Wells (35), however, cautions against this practice of fusing scores and remarks that "in borderline Binet ratings the Porteus scores may well be decisive from the standpoint of practical disposition." He prefers to consider the test

results separately, and "to estimate the proper bearing of each score on the understanding of the case." Herd (7) also counsels dependence in diagnosis upon the verdict of performance tests, and places the Maze "in the front rank from this point of view."

Earle, Milner and others carried out studies in England (4) to determine the usefulness of various tests in vocational guidance. Their subjects were 570 children attending elementary schools in a working-class district in London, whose median age was 13 years, 10 months. The boys' median Maze score was 12.4 years, girls' 12.1 years. They agree with Burt's previous findings as to the causes for failure, listing mental confusion, failure to sustain attention, inability to follow the longer paths on the mazes with the eye, failure to remember the course planned, inability to profit by errors. Other mistakes were due to overconfidence or careless or impulsive habits of action. The other tests used in this study were the Knox Cube, the Dearborn Form Board, the Cube Construction, Goddard Form Board, both Healy Picture Completion Tests, the Binet and a group intelligence test. In regard to the use of tests as predictive measures in industrial training, the Maze correlated .61 with "passing out" examinations for "Fitters." Though it appeared unlikely that the test results would have any significant bearing on industrial ability except at rather low levels, there have been some recent studies which support the relationship, at a higher industrial range. Gibbons (6), for example, became interested in the problem of selecting foremen for an Ohio Alkali Company by means of indirect measures of personality and found that weighted scores derived from an Employee's Record Form, plus a score based on the times taken for putting on and taking off nuts on a Bolt Board test, plus the number of stops made in working through three of the Porteus Mazes, correlated .632 with superior officers' ratings, and could be used as a prediction equation.

Brundage¹ also reports the use of the Maze in connection with the selection of foremen at a Wrigley Gum factory in Chicago. The problem was to select inspectors of boxes of their commercial product, involving the handling of about 1,000 boxes an hour. There was an experimental battery of twenty tests in which the

¹ In a private communication to the writer.

Maze was included. With N98, "the highest single correlation with criterion was the Maze T. Q., with .498." The same score on the Maze (taken without the subject's knowledge) was one of the highest, with about .44. After working out the multiple correlations Brundage "wound up with Porteus T. Q., Porteus Time, Placing (Minnesota Rate of Manipulation), and Number Checking (Minnesota Test for Clerical Workers). The uncorrected R was about .74. Porteus T. Q. carried the heaviest regression weight."

He continued this study by examining girls who passed the aptitude tests but failed on the job and noted a peculiar characteristic in their Maze performance. "The high-test, low-performance girls," he says, "for the most part, were characterized by 'shattering' on the Maze. They would go along all right until they made their first error, usually at about IX or X. Then they would lose their caution and grip on themselves, lose their personal composure, and start tracing at random. On the other hand, the high-performance girls would buckle down and intensify their concentration when such an error occurred." All experienced examiners are familiar with what Brundage calls "brittleness" in test performances, but its relation to industrial inefficiency has not before been so clearly pointed out.

The writer has never placed much emphasis on the use of the adult mazes, but it is evident that observation of reactions to failure are most important and the use of the more difficult designs will provide additional opportunities to note such effects. Some psychologists at one time were inclined to criticize the Maze because it depended on only one form of test material. The modern viewpoint is entirely the opposite. It is recognized that a test which requires fifteen to twenty minutes' intensive concentration of attention on a task involving the same mental set and mental capacities has a much closer relation to everyday requirements than the sudden spurts of mental activity involved, say, in a rote memory test or the definition of a word in a vocabulary list. In the Maze test, the basic data of the problem does not change as markedly as it does in a vocabulary test. In short, the homogeneous character of the data and the mental operations involved is one of the most advantageous features of the test. The constant repetition of the situations in which decisions

must be made affords the subject a chance to readjust his methods in the face of errors or increased complexity. He is proving his ability to deal with more complex relevant stimuli, which is of the essence of intelligent adjustment.

Morgenthau (11) investigated the statistical reliability of the various tests, using equivalent forms, and found the coefficient to be .95 for the Maze, .93 for the Binet. Some of the Maze intercorrelations were puzzling—.7 with the Thorndike Reading Test Alpha II, .7 with the Healy P.C.2, .54 with the Binet, but only .36 with the Pintner Non-Verbal. Weisenburg, Roe and McBride (34), in their study of adult hospitalized patients, also found the test relationships "puzzling." The highest was with the Printed Analogies Test (.62), followed by .59 with the Stanford-Binet, and .58 with the Pintner Non-Language. Even the Gates Oral Spelling Test correlated .41 with the Maze. Worthington's study (36) was concerned with the correlations of a group of tests, mainly of the performance type, with the Binet. The Maze correlated .75, the Seguin Form Board .76, the Healy P.C.2 .41, and the Knox Cube .56. Louttit (9) has tabulated some of the Binet-Porteus correlations and compared them with his own data on Indiana Clinic cases. He obtained coefficients between Maze and Binet of .61 for boys, .73 for girls. Gaw (5), using as subjects canal-boat children in England, obtained a Maze-Binet correlation of .52. The writer has summarized most of the studies prior to 1933 in his *Maze Tests and Mental Differences*.

Catholicity as regards relationship of the Maze with tests of the most diverse nature is certainly a marked and rather puzzling feature of this test. The correlation of the Maze with the Binet can, I believe, be accepted, for ordinary sampling of cases, to be between .6 and .7, but the relationship with other performance tests is somewhat surprising. Earle and Milner obtained correlations of between .3 and .4 with the tests they used, while Morgenthau found that even as non-intellectual a test as Tapping correlated .48 with the Maze. Peterson and Telford (13) examined Negro school children on the island of St. Helena off the South Carolina coast, and quote such correlations as .28 with the Goodenough Drawing, .51 with the Digit Symbol, in quite the reverse order to what might be expected. The average of all

correlations with the Maze was .42, the next highest average being .29 in the case of the Two Figure Form Board.

Vicary (32), who tested children of Indian aboriginal tribes at a mission school in Bengal, also found higher intercorrelations for the Maze than for other performance tests. The coefficients with the total of the tests used were .73 for the Maze, .66 for Cube Imitation, .57 for the Diagonal Test, .56 for Healy Construction A, .55 for Goddard Form Board, and .5 for the Triangle Test. An average of the coefficients of each test with the other five taken singly put the Maze in first place with .38, the Goddard Form Board second with .27, the Diagonal Test .25, the Cube Imitation .24, the Healy Construction A .24, and the Triangle Test .16. On the basis of g-factor loadings Vicary combined these tests in a battery with the following weighting: Maze 5, Form Board 2, Cube Imitation 1.

A reasonable interpretation of the above widely confirmed results would be that whatever capacities are tested by the Maze, these also enter to some degree into the successful performance of almost all types of test, verbal and non-verbal. Moreover, the intertest linkages seem closer with the Maze than for any other performance tests. The reason for this width of correspondence is by no means obvious. In common with other investigators, the writer has been surprised by some apparently inexplicable relationships. In general, it has always seemed remarkable that the ability to thread a way through a series of graduated maze designs should be related in any significant degree to social adaptability, into which so many capacities enter. The writer has come now to the conclusion that it is the *lack of uniqueness* of the test rather than its peculiar nature which provides the explanation. In other words, the only theory that seems to fit the facts regarding the catholic relationships of the Maze is that planning or prevision must enter into every mental task or mental operation. This is true of verbal tests also. We may state the conclusion in another way by saying that prehearsal of solutions is an essential part of every purposeful response. Even in such a test as a Stanford Vocabulary there must be a subvocal rehearsal before the overt reaction of framing the definition in words. Because planning enters into the operation explains why Weisenburg *et al.*

found correlations of the order of .3 and .4 between tests of this type and the Maze.

The notion of anticipatory excitations or prehearsals is basic to the writer's theory that all mental operations involve the setting up of neural circuits, or in psychological terms, that *all responses are circular* (23). Actions that require little or no planning are those that have become automatic or, in other terms, those activities for which the neural circuit is already complete. In situations which present multiple choices, the prehearsal takes a longer time and there is a greater delay in reaction. There are some specific tests of the capacity for foresight and planning, and the Maze is recognized rather generally to be predominantly a test of this nature. Because this planning is so fundamental in human activity, the Maze score is found to have the wide relationships that correlational studies indicate. Every valid test is to greater or less degree a test of planning capacity.

Any task which calls for visual and motor coordination necessitates the interplay of widely separated functional areas in the brain. There are few, if any, narrowly circumscribed neural circuits, and many mental operations such as the solution of a maze problem involve the major portion of the central nervous system. Hand and eye movements dependent on the motor area, visual interpretation, subvocal judgments are merely part of the mechanics of maze tracing, while memory and the sustaining of attention also enter into successful performance. Since fearfulness of failure and moderate anxiety are also typical of many individuals' reactions, the thalamus and hypothalamus are also involved, while cerebellar connections affect steadiness and motor control. In short, since this wide interplay is essential, good planning depends very largely upon a well organized neural system. Apparently the prefrontal areas play a very significant part in planning, because when 80 to 85 per cent of the subcortical connections of these areas with the rest of the central nervous system are cut by the operation of prefrontal lobotomy, there is a marked deficit in maze performance (24). The reason for the comparative failure of the feeble-minded to make good responses in the Maze resides in the presumptive fact that their brains are poorly organized, especially in the prefrontal areas.²

Other conditions which affect maze perform-

² See article on Prefrontal Lobotomy.

ance adversely have also been demonstrated, among them debilitating diseases such as hook-worm infection and vitamin B deficiency. In 1918 Waite and Neilson (33), working in North Queensland, demonstrated that both Binet and Maze performance were impaired in the lightly infected, and still more seriously in the heavily infected. In the eleven-year maze the hook-worm cases were slower, taking on the average nine seconds longer to complete the design.

O'Shea, Eldom and Higbe (12) induced vitamin B deficiency in a group of voluntary subjects. In addition to the Maze, the Henmon-Nelson Test of general ability, the Otis Quick-Scoring Test, the Thorndike-McCall Reading Test, a Tapping Test and the Healy Picture Memory Test were used. The authors' conclusion is that "deficiency of the B vitamins is associated with impaired ability to solve a series of mazes, that this impairment begins early in the deficiency and progresses as the deficiency deepens, and that it may be restored by the administration of either thiamine alone or the B complex." The control group, on the other hand, showed no significant variation throughout the observation period. A special point-scoring was used for the Maze which was re-applied in variously rotated positions to avoid practice effects. It is interesting to note, as the authors remark, that general intelligence, reasoning ability and tapping speed did not deteriorate in the vitamin deficient group.

There seems to be considerable support for the claim that the Maze comes reasonably close to being of universal applicability, regardless of cultural background, though Mann remarks: "This is a claim that is made for no other test (10)." Elsewhere in this volume³ results have been cited for such widely separated primitive peoples as the Luzon negritos, Borneo seagypsies (Bajou), Malayan mountain Sakai and coastal Sakai Jeram, Australian Arunta, Nyul-Nyul, Karadjeri, Iliaura, Keidja, etc., African Mchopi, Bathonga, Shangaans, Wakaranga, Vandau and Bushmen, all of whom accepted the test and worked most earnestly at it. Any psychologist or anthropologist with first-hand experience of primitive peoples would recognize the futility of attempting to apply a test which is quite foreign to the cultural set. His subjects would soon tire of it, and as Blackwood (2) has remarked with regard to the length of tests,

³ See article on Primitive Mentality.

it is a waste of time attempting to persuade a primitive subject to continue doing something after he has wearied of it. It is significant that the African Bushmen, who had the poorest average record of any primitive group, displayed extreme interest in the test (25).

Peoples of somewhat less primitive status showed equally keen interest in the Maze. Ainu boys from Northern Japan had an average quotient by the test of 106, Ainu girls 101, Formosan boys 102. Test quotients obtained by other groups were: Tamil coolies 94, Ghurkas (Nepal) 81, Ainu adults 93, Chinese Poorhouse inmates 83. Literate Chinese Poorhouse inmates scored 86. All other groups were illiterate, and were examined by Kilton Stewart (30). Wu (37) reports that Chinese primary school and kindergarten children numbering over seven thousand averaged at every level from 3 to 16 years of age about a half-year above their chronological age. He remarks, however, that the children were somewhat selected on the basis of intelligence and that testing conditions were faulty. On the other hand, Tsao (31) in Hopei province obtained an average T. Q. of 85 for Chinese subjects.

It is not contended that the Maze test is entirely "culture-free." One tribe, at least, in Africa (the Amaxosa) are familiar with a labyrinth game, the designs being drawn in the dust, but even so their records were below those of mission natives, though superior to those of other "raw" native tribes. It is also possible that peoples familiar with the making of string figures, a very popular pastime among some primitive groups, might possibly be helped in maze tracing, but that could only be proved by a special study on the subject.

The latest development with regard to the Maze has to do with its application to delinquents. It had been noted, in the first use of the tests with this class of subjects thirty years ago, that individual delinquents, though obviously maladjusted socially, sometimes scored well in the Maze. In 1922 the writer had stated (20) that the responses of these cases "may show qualitative differences from those of normals of equal test age," but nothing was done to follow up this lead.

In the meantime two studies, one by Poull and Montgomery (28) at Randall's Island, New York, and the other by Karpeles (8) at Providence, Rhode Island, showed that as far as

the general picture was concerned delinquents tended to have inferior scores on the Maze. The first-named investigators found that when a group of children with records of truancy, incorrigibility or stealing was compared with a self-controlled, diligent, cooperative group of children at the same hospital there was no difference between their Binet averages. In Maze test quotients the maladjusted group were 8.7 points below the well adjusted. The group differences in Healy P.C.2 average score were negligible.

Karpeles' two groups each numbered 185 cases and again the socially maladjusted were 8.27 points below the average of the control group. When the comparisons were confined to cases with Binet I.Q.'s above 80, the difference increased to 11 points.

In 1941 the writer began an analysis of qualitative errors, listing such things as cutting corners or crossing lines, irregular drawing, errors near the beginning or end of the test, lifting the pencil against specific instructions. Delinquents as a group made twice as many errors as non-delinquents, while adult criminals made three times as many mistakes as a group of one hundred bus drivers. The average error score of delinquent girls was 53, of non-delinquents 25. Delinquent boys scored 49 points, non-delinquents 22, criminals 57, bus drivers 18. The ordinary quantitative scores correlated with the qualitative scores, .44 for girls, .37 for boys (.25).

With assistance in gathering data rendered by Dr. Charles Honzik, the study was continued in 1942. In all, eighteen other groups were examined and the tabulated results completely confirmed the previous findings with delinquents and criminals. "Undependable" pineapple cannery workers, disciplinary problem children in schools, were also compared with appropriate control groups. The results with a discussion of the whole problem have recently been published (27). It is confidently hoped that these qualitative error scores will provide another approach to the detection and study of predelinquent children.

Briefly summarized, the results were that students at a high school who were reported to be careless in completing assignments or unsatisfactory for reasons other than mental dullness scored 32 points, as against an average score of 19. In an intermediate school the average was

23 and the unsatisfactory students averaged 48 points. The experiment was repeated at another intermediate school and the "undependable" pupils' score was again 48 and the average for the school was 22. One hundred delinquents averaged 56 points in qualitative error score whereas in the previous investigation their score was 51. Only one point separated the scores of the second group of criminals from that of the group examined in the first study. When analyzed, the results showed that men convicted of crimes of extreme violence such as murder, rape, and assault with a dangerous weapon had an average error score of 67 points, while those convicted of less violent but impulsive sexual crimes averaged 57 points. As might be expected the burglars were somewhat better with 54 points and the forgers and embezzlers had the distinctly better record of 44 points. The differences between the averages of the satisfactory and the undependable cannery employees were also completely reliable from the statistical standpoint.

PRIMARY ABILITIES.—It is universally acknowledged that mental ability is diversified so that men of equal level in mental endowment usually differ widely in what they can accomplish. Their particular aptitudes are called special abilities. The absence or low levels of the special abilities are sometimes called disabilities. Some of the well known among these groupings of ability are musical talent which often runs in families, artistic talent, mechanical ability, and verbal ability. These groupings are only roughly descriptive. When these are investigated experimentally they are found to be complex rather than unitary and it is an important psychological problem to ascertain how many fundamental abilities are implied in each grouping. For example, many thousands of musical tasks could be tried in appraising musical talent but it seems certain that they would be correlated and reducible to a smaller number of basic traits. It is equally certain that they do not reduce to a single musical trait. How many linearly independent traits are involved in this domain? That is the type of problem for which the multiple factor methods were developed.

In order to render intelligible the problem of identifying the primary abilities experimentally it becomes necessary to delimit each inquiry to a domain which is defined by a test battery of more or less related tasks. The factorial methods enable us to ascertain the number of linearly independent factors (abilities) that must be postulated in order to account for the observed correlations in the experimentally defined domain. It can be shown that this number is the rank of the table of inter-

correlations, regarded as a square symmetric matrix. When it has been thus determined that the intercorrelations of, say, thirty tests are of rank 5, for example, then the psychological problem is to identify these five basic traits which are responsible for the common variances in the test battery.

At this point there appears one of the most interesting forms of indeterminacy, the nature of which can be illustrated geometrically. In the geometrical model which has been found very useful for problems of this type, each test is represented by a test vector. In three dimensions these can be represented as long pins that are stuck into a central cork. The square of the length of each pin represents the fractional part of the variance of a test which it shares with other tests in the battery. A very short vector would then represent a test that has very little of its variance in common with other tests in the battery. A vector of unit length would represent a test which has no unique variance, since all of its variance is shared with one or more of the other tests in the battery. If three factors were sufficient to account for the intercorrelations in the test battery, then the whole table of correlations could be represented by a physical model with pins in a central cork. Each pin would represent a test. The correlation between any pair of tests would then be the scalar product of a pair of test vectors. No information would be lost in constructing such a model from the correlations which could in turn be reconstructed from the angles and the lengths of the vectors in the model.

The psychological problem is to identify the three fundamental abilities from the model if it is known experimentally that the rank of the intercorrelations is 3. The rank of the correlations is the same as the dimensionality of the model. In every factor problem we encounter just this situation in which the intercorrelations determine the configuration of the test vectors without any reference frame. The problem of identifying the fundamental abilities in the test battery is then geometrically the same as locating a suitable and meaningful reference frame in the model. If the test vectors are found to be arranged in a triangular configuration, then the most plausible location of the three reference axes is at the corners of the triangle. Sometimes these fundamental axes are found to be uncorrelated, i.e., at right angles in the

model, and sometimes they are correlated, in which case they are separated by acute or obtuse angles. The acute angles represent positive correlations.

When the problem has been solved, either geometrically or in the equivalent algebraic form, then it is possible to prepare what is called a factor matrix which describes each test in terms of the basic factors. An opposites test would then be described as having a large saturation in one of the verbal factors and perhaps zero saturation in some of the visual factors. An arithmetic reasoning test would be found to have saturation in several factors but it would probably have zero saturation on verbal fluency. When the resolution into basic abilities has been effected by these analytical methods, either geometrically or algebraically, the final test of scientific fruitfulness is in the meaningfulness of the factors or abilities that are so isolated. As long as they are arbitrary, they remain merely statistical artifacts of very little use for psychological science. But when they can be interpreted as psychologically meaningful aspects of perception, association, and thinking, then they become landmarks in our slowly advancing understanding of mental organization.

An equivalent statement of the problem is to consider first how many factors must be postulated in order to account for the experimentally observed intercorrelations. That is the rank of the intercorrelations. The next problem is to describe each of the tests separately with the smallest possible number of factors. When that has been accomplished we have the same solution as that which is obtained configurationally by the geometrical interpretation. The solution involves then two successive steps in parsimony but their scientific validity must be ultimately sustained by the test of all scientific experimentation, namely, our ability to comprehend the significance of each factor as a parameter determining the test performance; and our ability to predict the factorial composition of a new task by purely psychological considerations about the nature of the factors. Several of the primary mental abilities have already been subjected to such verification with gratifying results. Some primary mental abilities have been identified with sufficient interpretation to make them useful in describing mental endowment with a profile, but they constitute so far only

a small beginning of eventual exploration in this field.

The primary mental abilities so far identified with some confidence are number ability *N*, visualizing ability which has been called the space factor *S*, memorizing ability *M* which is probably distinct from incidental memory and several others such as visual memory, verbal comprehension *V*, verbal fluency *IV*, induction *I*, speed of simple perception *P*, another factor that facilitates speed of perceptual closure, another factor that facilitates flexibility of closure, and two verbal factors, one of which facilitates association within restriction on the form of the response and another that facilitates association with constraint on the meaning of the response, and a naming factor which may be related to the verbal fluency factor.

There is indication also of one or more general intellectual abilities that underlie the primary mental abilities and which account for the inter-correlations of the primary mental abilities. It seems likely that the correlations between the primary mental abilities will sustain the early work of Spearman who postulated a central intellectual factor in addition to the special abilities.

It seems reasonable to expect that vocational and educational counseling will eventually be accomplished with the aid of tests assembled rationally rather than, as at present, with crude empirical investigations of the validity of each test for every possible type of criterion without rational foundation.

L. L. THURSTONE,
University of Chicago

PRIMATE PSYCHOLOGY.—The mammalian order of primates includes man, the anthropoid apes, Old and New World monkeys, tarsier, and lemurs. Except as otherwise indicated, the term "primates" will be used in this article to designate the infrahuman primates; "apes" will refer to gorilla, chimpanzee, orangutan, and gibbon; all the lesser primates will be referred to as "monkeys." It should be borne in mind that most of the available experimental data and much of our observational information have been derived from a few of an uncertain but large number of species. What is said about "primates" or about "monkeys," therefore, must be understood to apply with

certainly only to those forms about which we have knowledge.

The role and value of comparative psychology in the field as a whole have been discussed frequently and require little elaboration here. The salient facts are (1) that by virtue of sheer numbers and diversity of forms, most of the behavior that occurs is infrahuman behavior; (2) that basic mechanisms or principles of behavior are often more discernible in simple than in complex organisms; (3) that animals may be controlled in ways not possible with human subjects; and (4) that knowledge of phylogenetic development furnishes valuable clues regarding the nature of the end product. Among animals, the primates occupy a uniquely important position: They are on one side of the widest gap in the continuum of phylogenetic development that separates man from the highest infrahuman animals. They form the connecting link, therefore, between human and animal psychology. In this strategic position, they provide the most immediate point of attack in tracing the origins of human behavior. Primate psychology has had a balancing effect in counteracting the still-present tendencies (1) to demarcate human behavior sharply and qualitatively from that of other animals, and (2) to accept uncritically anthropomorphic interpretations of infrahuman behavior. Primate behavior is so similar to that of man that recognition of the continuity is inescapable in spite of the obviously great differences in quantity or degree along certain directions.

To trace the influences of primate psychology on psychology in general is beyond the scope of this article. That such influences have been frequent and critically important can hardly be questioned. Just a few examples must suffice. The acute observations and experiments of Köhler at Tenerife have had far-reaching effects on his own general psychological theorizing and, directly or indirectly, on that of all other psychologists; one need think here, for instance, only of such concepts as "insight" and "the restructuring of the psychological field." Influences and contributions of more modest and limited extent are extremely numerous: Several techniques (e.g., the use of token rewards), developed for the testing of behavior phenomena in the non-verbalizing chimpanzee, have been found useful in experiments with human

subjects. McCulloch's careful study of grasping behavior in chimpanzee and his analysis of the results, pointing to excitement- or tension-reduction as the mechanism of reinforcement, will or already has exerted a definite influence on the understanding of human learning.

The materials of psychology, behavior of the organism-as-a-whole, may be classified according to the situations in which it occurs: maze, problem box, Umweg, social—or according to explanatory categories: conditioning, memory trace, vectors, perceptual structuring, glandular insufficiency. Many other forms of categorization are possible, but these are among the main ones and serve to represent the choice between "operational" description and explanation. It would be very satisfying to have a survey of primate psychology organized entirely according to explanatory concepts, following the ideals of a program such as that recently suggested and initiated by Hull. This would mean that "social psychology" would drop out as a topic and that the data from social situations would be treated in connection with each of the basic psychological mechanisms or principles involved. The objections to such a consistently explanatory approach to primate psychology at this time are the relative paucity of factual raw materials, the incompleteness of our psychological analyses, and the consequent divergencies of opinion regarding explanatory concepts. In the following treatment the materials are organized under what the writer considers psychologically meaningful categories. For ease of identification, situational terms are introduced in many of the subheadings. Highly specific explanatory concepts are avoided in favor of more general or descriptive ones. It is obvious that for purposes of detailed experimental investigation it is usually necessary or desirable to "translate" or "reduce" the latter to more precise, testable formulations. Finally it may be noted that the distribution of space and emphasis reflects a judgment concerning (1) the amount of information available and (2) the relative importance, in *primate psychology*, of the various topics treated.

No attempt is made to dichotomize sharply the innate and experiential elements in behavior. Such factors as sensory acuity and motor capacities are admittedly dependent to a high degree on inherited structure, but so is the po-

tentiality for alteration of behavior through experience, for generalization, for abstraction, and for integration of present and past elements of experience. Compared to that of other animals, the behavior of man is relatively "free" and varied; a given sequence of stimulus situations does not ordinarily evoke rigidly and specifically determined, uniform responses. In this respect the infrahuman primates occupy a position between man and the lower mammals, the apes (at least chimpanzee and gorilla) probably approximating that of man more closely than do the monkeys. Where credible and important evidence exists for the essential innateness of a significant behavior pattern or for the critical role of prior experience, this is indicated in the text.

SENSORY CAPACITIES

The avenues of contact with the external environment are highly similar among the various primates, including man, the greatest deviations being found in the tarsiers and lemurs.

Chemical sensitivity. Together with the whales, the primates are distinguished from other mammals by a relatively poorly developed olfactory apparatus. Although there has been almost no experimental work on the subject, observations of behavior in the field and in the laboratory confirm the anatomical indications that the sense of smell is not significantly better—or worse—in the monkeys and apes than in man. The fact that chimpanzees, for instance, often examine objects by bringing them close to the face (or the face close to them) may be misinterpreted as evidence for the prominent role of olfaction; such behavior probably serves mainly to permit tactual (lip) and close visual inspection. Although the sense of smell doubtless plays an important part in the selection of food, it seems to have a minor function in the search for food and in the detection of enemies and other dangers. Its importance in sexual behavior is uncertain. On the basis of structural rather than behavioral evidence it appears probable that the tarsier and especially the lemur may have some advantage over the other primates in respect to olfactory sensitivity.

The only experimental study of gustation (Patton and Ruch) indicates a differential sensitivity to various concentrations of quinine

which is closely similar for man, chimpanzee and macaque. Chimpanzees frequently reject food (especially milk and eggs) which is slightly spoiled. The same individuals may, on other occasions, accept extremely bitter substances when these are combined with a well-liked food such as grape juice or candy.

Audition. The lower intensity limen at various wave frequencies has been carefully determined for young chimpanzees (Elder) and for three species of adolescent and young adult monkeys (Wendt). From 64 to 128~ to about 2048~ the sensitivity of apes and monkeys was found to be quite similar to that of young adult human subjects. An apparent slight superiority of the chimpanzees may be attributable to their lower relative age. At 4096~ monkeys and apes show a marked diminution of acuity as compared to man. The reasons for the "4096~ dip" are obscure; in human subjects a general deterioration of acuity for high frequencies often begins with loss at this particular point. At the higher frequency of 8192 the relative sensitivity of the animal subjects increased considerably. This advantage (lower threshold) as compared to man was maintained by the monkeys at the still higher pitch of 16,384~. The greater acuity of subhuman primates in terms of intensity limens at high frequencies is consistent with Elder's finding that his chimpanzee subjects were responsive to tones ranging up to 26,000 to 33,000~ whereas children of comparable age had an upper limit of 22,600 to 23,700~.

Similarly careful investigations of pitch and intensity difference limens have not been made; preliminary studies along this line indicate that the training necessary for such determinations will be difficult. In chimpanzee, at least, localization of sound seems to be of about the same order of accuracy as man's. No controlled and systematic study has been made of primate ability to discriminate complex sounds such as of the human voice; in the reports on pets and stage performers the possibility of response to other cues, such as gestures, temporal routine, and so on, has not been excluded.

Vision. Spence has shown that the visual acuity of chimpanzee is quite similar to that of man. In terms of the visual angle subtended at the eye by the least perceptible width of lines (using the Ives test objects) the 75 per cent threshold values for chimpanzee ranged from

4.57 to 0.47 minutes, whereas for human subjects the corresponding values were from 3.09 to 0.44 minutes. As in man, visual acuity of the chimpanzee varies directly with the logarithm of brightness of the test objects, at least within the range of 0.00138 to 3.98 millilamberts. There is some indication that in man and chimpanzee acuity decreases at very much higher brightness levels. Weinstein and Grether's study of rhesus monkeys and Johnson's experiment with the cebus monkey indicate that the minimum separable acuity of these primates is of the same order as that of man and chimpanzee. Preliminary tests made by Klüver by the "minimum visible" method with Java monkeys indicate a visual acuity lower than, but probably not significantly inferior to, that of the aforementioned primates. Grether has shown that the slight superiority of man over chimpanzee and rhesus monkey is further reduced when differences in eye-size are taken into account and acuity is calculated on the basis of retinal image width rather than of visual angle. This fact is of physiological rather than behavioral significance, since the eye as a whole and not only the retina determines what the animal sees.

Limens for brightness discrimination of rhesus monkeys were determined by Crawford. At levels of 0.77, 7.1, and 55.3 millilamberts the monkeys discriminated brightnesses differing by about 11 per cent with 75 per cent accuracy; at 0.08 millilamberts a difference of 36 per cent was necessary to obtain this degree of accuracy. Adult human subjects met the same criterion with a fractional brightness difference of about 11 per cent at the 0.08 level and of about 7 per cent at the higher brightnesses. That is, the monkeys were slightly inferior at brightnesses of 0.77, 7.1, and 55.3 millilamberts but were definitely inferior at the lowest level. It may be that the adaptation level of the monkeys was not as favorable as that of the human subjects at the 0.08 millilambert brightness and that this fact is largely responsible for the greater discrepancy at this point.

The careful and extensive investigations of Grether indicate that the color vision of chimpanzees differs only slightly from that of the normal human trichromatic eye. Hue discrimination is equal to that of man in all parts of the spectrum excepting at wave lengths longer than 600 mμ where the limens of chimpanzee

become roughly twice as great as for man. The evolution of color vision mechanisms has apparently progressed a little further in man by permitting somewhat greater differentiation at the long wave-length end of the spectrum. The spectral limits of chimpanzee (402 to 704 mμ) are as wide as those of man. Tests with color mixtures indicate that sensitivity to longer spectral wave lengths is equal for man and chimpanzee, but that there may be a relatively reduced saturation of red (610 mμ) for the chimpanzee. Experiments with several species of Old World monkeys and with one female spider monkey indicate that the color vision of these animals is roughly equal to that of man; if there is any difference it is in the direction of slightly reduced sensitivity and hue discrimination capacity in the yellow and red regions. Three male cebus monkeys yielded results comparable to those of human dichromatic vision of the protanopic type; it is possible that this deficiency is a species characteristic or that in these monkeys, as in man, dichromacy is limited largely to males of the species. It is highly probable that in the nocturnal lemurs and in tarsius color vision is completely absent.

Other sense modalities. Observations strongly indicate that chimpanzees, and probably the other primates as well, are much less sensitive to pain than is man. This conclusion obviously is based on the infrequency of behavior interpretable as expressing pain; in view of their free and ready emotional expressivity, it hardly seems likely that these animals would inhibit reactions to what we know as pain. Animals with severe wounds sustained accidentally or in a fight show few signs of discomfort and go about their business in normal fashion. Visceral pain, such as that accompanying parturition and dysentery, or following a major abdominal operation, elicits somewhat greater response. One adult chimpanzee, however, with multiple intussusceptions, probably of several months' standing, gave no observed signs of discomfort until a few hours before death. Some individuals pluck out their own hair until they are practically naked; others, with pinworm infestation, pick at the anus until it is bleeding freely.

McCulloch has shown that young chimpanzees could discriminate a 9.2 per cent difference between two weights (at the level of 80 grams) with about the same degree of accuracy (75 per

cent) as is achieved by human adults. Using the pulling-in technique with Java monkeys, Klüver obtained 90 per cent accuracy when the effective masses differed by an estimated 30 per cent at the 125 gram level. The skill exhibited by most primates (least of all by the gorilla) in arboreal locomotion attests a well-developed sense of balance, similar, perhaps, to that of a highly trained professional acrobat.

Although their skin is relatively thick, the tactual sensitivity of many primates appears to be fairly keen. Grooming activity in the chimpanzee and various monkeys, although aided by vision, indicates a high degree of precision in tactual localization. One of Klüver's cebus monkeys was able to find a thread of 0.204 mm. diameter in complete darkness. Kohts' chimpanzee identified geometrical shapes by manipulation. In chimpanzee the most sensitive areas are probably the lips.

Except for such casual observations as that temperature extremes are avoided, nothing is known about the temperature sense in primates. Observations in the field indicate that chimpanzees may communicate with each other by pounding on the ground or against a tree trunk, suggesting the possibility of a well developed vibratory sense.

MOTOR CHARACTERISTICS

Locomotion and posture. Climbing and arboreal locomotion are common among all primates except the baboons, who are completely terrestrial, and the gorilla which spends most of its time on the ground. Pronograde progression is the general rule, usually with the trunk above, but not infrequently suspended below, the limb. Brachiation, a specialized form of underslung locomotion, is preferred by the gibbon and is seen also in some of the monkeys, especially the New World spider monkey. On the ground, quadrupedal locomotion is invariable in the baboon, usual for most primates, rare in the gibbon. The weight of the body rests on the soles (or outer edges) of the feet and on the middle knuckles of the fingers in the case of the great apes, on the soles and palms of the other primates. Orthograde, bipedal walking is seen most frequently in the gibbon, less often in gorilla, chimpanzee, and orang. Suspension of the viscera in the anthropoid apes is similar to that in man and favors an upright posture in sitting and walking; in monkeys the viscera

sag to the bottom of the abdominal cavity when the trunk is in a vertical position. Most of the monkeys probably are able to swim; the evidence for this ability is definitely negative for the gibbon and chimpanzee.

Manipulative skill. The primates are distinguished for the skill and especially for the variety of ways with which they can manipulate the environment. The hands, feet, lips, teeth (and, in the case of many of the New World monkeys, the prehensile tail) contribute to this ability. In comparison to man, the skill of the feet more nearly approximates that of the hands; and laterality is less dominant. A given individual usually has a preferred side, but this apparently is as often the left as the right side and may be different in different activities. Eye-hand coordination and the precision of delicate movements in such "natural" activities as grooming, are especially remarkable in view of the greater thickness of fingers as found in chimpanzee. Much of the awkwardness which appears in artificial situations is probably a function of limited practice and may be overcome by training procedures. Relatively little serious work has been done to determine the ultimate capacities of primates in motor skills. Thumbs and great toes can be rotated and opposed to the outer digits in all the primates having thumbs. (Thumbs are absent or vestigial in the New World spider monkeys and in the colobus monkeys of Africa.) As compared to man, however, thumb-finger opposition usually serves gross movements, such as the grasping of a limb, rather than fine prehension. In picking up a small pellet, for instance, the chimpanzee tends to use a pincer-like movement of the second and third fingers.

Speed and strength. Measurements of simple reaction-time of young chimpanzees (Forster) give values similar to those for human children: about 243, 223, and 206 milliseconds for visual, auditory, and tactual stimuli, respectively. It has been estimated that on the ground baboons can travel almost as fast as dogs, and that for short distances the speed of gibbons brachiating through trees may be as great as that of a fast human runner. All primates and especially the great apes give the impression of being very strong and it is true that four men have great difficulty in holding down a five-year-old chimpanzee when the latter is highly excited. On the other hand, measurements of muscular

strength in the calm but well-motivated chimpanzee give indices which, in proportion to body weight, are similar to those of man (Finch).

SOCIAL FACTORS IN BEHAVIOR

Groupings. Most of the primates are notably gregarious creatures. The adult male orang is perhaps the least social of the primates, according to report, living by himself most of the time and meeting with his females and their children only occasionally for the purpose of mating. Gorillas and chimpanzees live in family groups comprising about 4 to 14 individuals: a large male, several adult females, and children ranging from infants to young adults. These groups are nomadic, but the extent of their wanderings has not been determined. According to Carpenter, the gibbon lives in family groups of 4 to 6 animals, a number of such families being banded together and having a territorial range of 30 to 100 acres. The baboons are usually found in troops of 30 to several hundred, each troop comprising numerous family groups. The common rhesus monkey is found in groups varying in size from 2 to 150 or more individuals, the number of females always exceeding the number of males. Carpenter has made careful population studies of two New World primates, the howler and spider monkeys. The former live in clans of 4 to 35 animals (average 17), each having a very definite territorial range. Spider monkeys congregate in groups of 30 to 40 at night, but these often divide into subgroups of 3 to 17 during the daytime. The tarsier and aye-aye are usually found in pairs (male and female), sometimes with an infant.

Dominance. In the relationships within primate groups dominance of some degree is a common feature. Its expression, however, varies widely. Among the baboons, according to Zuckerman, it is very direct: sheer strength and fighting ability determine which one is to get the food and which one is to mount the female. In these fights it is the females rather than the males who carry off most of the scars of battle. Although it can perhaps be stated as a general rule that among primates males tend to be dominant over females, this may be more a function of size (the males usually being larger) than of sex *per se*, and it is a generalization which has many exceptions. Among the New

World howler monkeys described by Carpenter, for instance, the female in oestrus takes much of the initiative and selects the male of her choice; if one male does not respond to her solicitation, or has been satiated, she passes on to another male. Overt fighting is rare among the howlers, gesturing and noise-making substituting for actual combat. The dominance-status between chimpanzees is sometimes decided by physical combat, but much oftener by "common consent," such agreement being preceded sometimes by bluffing and exhibitionistic behavior, sometimes by extremely subtle, almost unobservable, gestures, postural attitudes, and vocalizations. Maslow, pointing out that dominance in one activity (e.g., food-getting) does not necessarily mean dominance in some other relationship (e.g., sex), suggests the need for specific terms, such as food-dominance. In general, there does seem to be a positive but imperfect correlation of dominance in various fields or aspects of social behavior.

Cohesive factors. Some friction or conflict of individual interests may be seen in almost any primate social group. The positive factors, bringing and keeping the members of a group together, are doubtless numerous and vary from general to specific. As with any organism, differences in environment operate to concentrate members of a species in the more favorable habitats. Satisfaction of the sex and parental (especially maternal) drives specifically demand a social milieu. There is safety, or at least the feeling of safety, in numbers. (Whether innate or experiential factors are the more important here is uncertain.) It is probably true that a natural enemy would be more hesitant about attacking a group of apes than an isolated individual. In most if not all wild primate groupings observed, a common front of defense is presented to the outside threat. Even when this endures only during the preliminary stages and disintegrates if the attack becomes actual, it usually serves its purpose. Wild chimpanzees have been seen to come to the aid of companions (especially of infants and children) even at risk of their own safety. A group of captive chimpanzees is much more dangerous to the human observer than are the individuals composing it; if one of the group becomes fearful or angry, it gives a cry which acts like a trigger to set off an attack by all. In general, however, the primate group acts as a group defensively

rather than offensively. Young chimpanzees, in whom the sex and parental drives presumably have no importance, manifest a "social need" even more than adults. They become extremely excited and distressed if deprived of their companions and under these circumstances are likely to become attached to their human caretaker. Infants raised in isolation from their kind become very jittery animals unless the substitutes for the ape mother expend a great deal of time and helpful attention on them. The young of all primates have more or less prolonged periods of dependence. The chimpanzee does not locomote effectively until the age of six months or later and derives its main nourishment from the mother's milk for at least the first year of life. The early care of the infant is mostly maternal, but later the father and other members of the group take part in playing with the youngster. Among gibbons, too, the paternal role is fairly important, changing from a playful, protective, and helpful one to antagonism in the case of male offspring approaching maturity.

Grooming and food-sharing. Aside from the biologically primary functions which are enumerated above and which are rather generally applicable to most of the mammals and to many inframammalian animals, grooming (often spoken of as "flea-picking") of one individual by another is the most frequently observed form of constructive relationship among primates. Yerkes assigns it great importance as the possible precursor of many "social services" appearing later in phylogenetic development. In chimpanzees, the typical pattern of grooming behavior appears among nursery-raised youngsters who have not had opportunity to observe the behavior of adult animals.

Most captive chimpanzees become friendly with their cagemates, and among such animals there is ordinarily peaceful and fairly equal sharing of the food supply. If two such animals are placed in adjacent cages, separated only by widely spaced bars, and the entire supply of food is made available to one, a good share of the food will be transferred to the partner. Such transfers will occur in one or all of three ways: (1) By accident or intent the "rich" animal spreads the supply around in his cage so that the "poor" one can get some by reaching through the bars. (2) The second animal begs or solicits, usually by stretching out an

arm horizontally and making rapid upward flexions of the fingers, often whining or whimpering at the same time; sooner or later the first animal usually responds to this begging by handing or tossing over a piece of food. (3) Sometimes the "rich" animal hands over food at times when the partner is not begging. On occasion an animal will tease his partner, starting to hand him a bit of food and then withdrawing before the transfer has been completed. There is evidence that wild chimpanzees will toss fruit down from a tree to a member of the group which, because of illness or injury, cannot climb the tree.

Cooperation. There is little evidence of teamwork or cooperative problem solving among wild primates—less, probably, than in some insect societies. Crawford trained young chimpanzees to work together in pulling in a food-baited box which was too heavy to be moved by one animal alone. Each partner had first learned the task individually. The great difficulty for the chimpanzees came in coordinating their efforts, in learning to pull at the same time instead of successively. This difficulty was eased by a verbal command from the experimenter to which the animals had previously and independently learned to respond by pulling. Later, the command could be omitted.

Communication. Most of the primates are noisily vocal creatures, but it is most doubtful that any of these vocalizations may be thought of as "language" in the sense in which the term is applied to man. The vocal apparatus of the anthropoids is similar to the human, but attempts to teach them to "speak" have met with little success. Efforts to train the apes to respond differentially to the spoken commands of man have been less successful than with dogs. Whether the reasons for this limitation are to be sought in differences of kind and degree of motivation effective with wild *versus* domesticated animals, in the great prepotency of the visual sense at the expense of the auditory mode, or in certain characteristics of the peripheral or central nervous system, is uncertain. The vocalizations which do occur—relatively infrequent in the gorilla, frequent and extremely varied in chimpanzee, frequent but with fewer variations in the monkeys—are emotionally expressive; they are responses to vitally significant situations. Their meaning being "understood" by other members of the group,

they have a communicative function. The cries of alarm and of anger, the vocalizations accompanying food-begging and sex-solicitation, the grunts associated with something pleasant, are responded to appropriately by others of the species. The communicative efficacy of vocalization is, however, general and "releasive" in character, rather than specific and "directive." The available evidence suggests that vocal communication may be more highly developed in some infraprimate societies (e.g., birds) than among the monkeys and apes. In chimpanzees, directive communication is largely gestural and postural, as seen in the following examples.

The adult male having discovered a group of human beings hiding in a natural blind, at once hurries to a tall tree in which a female with her infant, who have been under observation, are resting; he climbs the tree and with his hands turns the trunk and then the head of the female until she is looking straight at the hiding place; then he climbs down with the infant, the female following and they all disappear silently into the forest. Jack, a caged adult male, has an erection and, as the observer passes, he pounds with a foot against the door leading to the adjacent cage containing a receptive female, at the same time smacking his lips and pointing with a finger through the wire mesh at the padlock which keeps the door closed. After the two chimpanzee partners have learned to coordinate their efforts in pulling in the heavy box in the previously described experiment on cooperation, the motivation of one is radically reduced by satiation with the kind of food used as a lure on the box. The still hungry animal tries to persuade the partner to work, putting a hand on his shoulders and guiding him to the working side of the cage, then placing the rope into the partner's hand. The directive gesture of begging has already been described. In perception of the intent and attitude of their fellows and of their human contacts, chimpanzees are astonishingly keen; minimal changes in facial expression or posture in one individual influence the actions of a cage mate. The lack of language, of an organized, conventionalized system of symbols certainly is the most striking behavioral difference between man and the lower primates; it may well be that there is an intimate relationship between the development of the communicative aspect of language and its function in problem-

solving ("thinking" or "reasoning") which is discussed below.

Certain other aspects of social behavior are considered in the following sections.

DYNAMIC ASPECTS OF BEHAVIOR

Activity level. With the partial exception of tarsiers and some of the lemurs and primitive monkeys, most of the primates are very active animals. Even in youth, before the serious business of earning a living has started, and in captivity where most wants are supplied without effort, a high level of activity is maintained. There are, of course, considerable individual, species, and age differences in this respect, the chimpanzee being more active than the gorilla and young individuals generally more so than adults. Quite aside from ends, goals, objectives, or rewards to be attained, the potentiality for behavior seems to provide its own impetus for overt expression or realization. The young captive chimpanzee (and this applies to a considerable extent also to the wild animal) exhibits a tremendous variety of "play" behavior, inventing endless acrobatic games—somersaulting forwards and backwards, gyrating like a moving, spinning top, with hands extended gracefully over the head, holding to a wire partition and then flipping over backwards to the ground, climbing out on a limb to its outer end until it is sagging down to where the animal can drop safely to the ground or to a lower limb, and so on, endlessly; finding new ways of eating and drinking—peeling a grape and eating the inside first, the skin later, taking a mouthful of milk, spilling it on the concrete floor and then lapping it up, soaking a hard cracker under the water faucet before eating, voluntarily regurgitating and then reingesting food; discovering novel ways of looking at the world—by standing upside down or bending over and peering through the legs, by punching a hole in a leaf and, holding the leaf close to one eye, looking through the hole, by producing a puddle of urine and gazing at the reflections therein; decorating the body with a stray piece of cloth or rope draped around the neck, keeping himself clean by endless self- and heterogrooming; examining strange objects in minutest detail and tearing them apart down to the smallest possible fragments; provoking social response in members of the same or other species by teasing, bluffing, attacking, spitting,

throwing sand or feces, or by friendly overtures of kissing, "tandem walking," and even the gift of food, a loose bolt or stick. Any or all such items of behavior may of course be subsumed under various drives or needs—of curiosity or exploration, gregariousness, and so on—if such categorization seems helpful. To be stressed here are two facts: (1) that chimpanzees tend to be doing something most of the time, and (2) the diversity of these activities. These characteristics obviously are the *sine qua non* for intelligent behavior on the higher levels of complexity. A third fact, which doubtless has much to do with the limitations of primate behavior, is that with few exceptions (grooming and certain tics and stereotypies) they do not stick at any one activity for any length of time. Their "power of concentration" is low. Kinder found that in the age range of one to three years chimpanzees in a rather stimulating environment changed from one activity to another once every 10 seconds or less.

Fear, maternity, companionship. Little or nothing has been done to obtain indices of the relative strengths of various drives in the primates. They are discussed here in an estimated order of decreasing intensity. Responses of the fear-anger class certainly have prepotency over any others. That is, whatever else the animal may be doing at the time will be abandoned in favor of flight or self-protection. (This probably is true of all animals, including man, but is especially evident in the monkeys and apes because they are afraid of so many things and because their chief mode of dealing with dangers is to run away from them.) Under normal conditions, the maternal drive is probably one of the strongest of the motivating forces directing primate behavior. In captivity it sometimes happens (especially among primipara) that a chimpanzee will abandon her infant completely, or will give it only half-hearted care, but the usual picture is one of devoted attention and jealous protectiveness. As was mentioned above, the need for companionship seems very great indeed in most of the primates. The external condition satisfying this need, however, seems to be determined by experience. Infant chimpanzees reared in isolation from their kind are indifferent to each other for weeks or months after they have been placed together. Infants raised in a human social environment may continue to prefer human companionship to that

of their fellow apes long after they have been caged with other chimpanzees. There is even a suggestion that early attachment to human companions may interfere with the later development of normal sexual behavior in the male chimpanzee. Young chimpanzees have strong and lasting preferences among their companions as has been shown by Nowlis. That the "pinning away" of an animal after removal of a favorite companion (of the same or other species) is more than a myth is suggested by observations in several instances.

Sexuality in chimpanzee. The strength of the sex drive in chimpanzees is difficult to evaluate. The extensive studies of Yerkes, Elder, and others indicate that the female is receptive only during the phase of sexual skin tumescence, about 10.4 days of the 35-day (average) cycle. It is believed that ovulation occurs near the end of this phase, when tumescence and receptivity are at maximum. Copulation at other times of the cycle (during detumescence, including menstruation), when it occurs (infrequently among friendly animals, more often when the two individuals are hostile or are strangers), has been interpreted as rape or prostitution in exchange for freedom from attack, for food, or for other favors. Individual females differ considerably in manifestations of the sex drive; some solicit the male frequently whereas others appear merely to submit to the demands of the male. Two adult females are on record who never allowed the male to mount. The pattern of mating behavior is highly uniform in the female chimpanzee, and this complete, typical pattern has been observed in a young individual on the first occasion after puberty when she was caged with an experienced male. Masturbation, usually manual but sometimes utilizing fixed objects of the environment (e.g., a water faucet), is very frequent in a few captive specimens) becomes fairly common, methods of stimulation being diverse: the hand, great toe, mouth, wire grill, floor, or another animal may be used. Masturbation usually disappears in the adult male if females are available, but may persist, rare or absent in most.

The male chimpanzee shows more variability in sex behavior than does the female. Erections are frequent in infancy, especially at feeding time, and during childhood whenever there is excitement of any kind. Towards the latter part of childhood masturbation (without ejacula-

persist or reappear if he is caged alone or with other males. Individual males vary greatly in their readiness to mate as they reach adulthood. Some copulate promptly and frequently at the first opportunity; others seem not to know what to do in the presence of a fully receptive female and the first mating may not occur for months or years after this might be expected on the basis of age and physical development. Some males will mate rather indiscriminately with any female at almost any time during the cycle, whereas others are highly selective, both as to individual females and as to the phase of the female cycle (Yerkes, Elder).

The dominance of the female chimpanzee is significantly greater during tumescence than during the period of detumescence (Yerkes, Nowlis, Crawford). In a competitive food-getting situation, for instance, the female in swelling will ordinarily, as a matter of course and without protest from the male partner, take precedence. As soon as detumescence sets in the roles are reversed, as it seems by common consent, and the male takes priority. This is the rule to which there are many exceptions in various pairings.

The hunger drive. The hunger drive and the incentive or condition which satisfies it lend themselves more conveniently to quantitative control and variation than do any other motivating conditions. Most of the experimental work on motivation has dealt with influence of different kinds and amounts of food reward on physical and mental work and on learning. Casual observation indicates that the efficiency of various activities, including especially discrimination learning, is greater when chimpanzees are moderately hungry than when satiated or starved for longer periods of time. This has been confirmed recently by Birch in a systematic investigation; under conditions of extreme motivation the attention of the animals was focused so intensively on the goal that other features of the situation, which provided the means to the goal, were overlooked. With some chimpanzee subjects it has been noticed that success in a problem can be its own reward; given all the banana it could eat before a training session, one animal worked enthusiastically for 60 trials, improving its mastery of a discrimination problem during this time. At the end of the session 60 pieces of banana, used as "reward," were found uneaten in the work-

cage. In tests of bodily strength Finch discovered that with a food-deprivation period of 24 hours *versus* "normal hunger conditions" two chimpanzees refused to pull, "three bettered their 'normal' records; one pulled the same under both conditions; two pulled less." In tests of food-dominance with pairs of chimpanzees Nowlis found that satiation of the normally dominant partner increased the proportion of food obtained by the subordinate partner and that the amount of food obtained by the latter was a function of its own hunger drive (as determined by length of the deprivation interval).

Incentive factors. Fletcher has made an elaborate analysis of performance (pulling against the force of gravity and of an electric brake in order to obtain a food reward) by young chimpanzees as influenced by the size of the incentive. With a fixed resistance, the frequency of response could be increased from zero (refusal to do any work) to 100 per cent (overcoming the resistance at every opportunity) by increasing the size of the incentive; an ogive curve represents this relationship. An approximately linear relationship was found between size of the incentive and the maximum work which the animal was willing to do in order to obtain it. Maslow and Groshong tested a gibbon and several species of monkeys in the delayed reaction problem and found that efficiency of performance was greater for preferred than for non-preferred kinds of food-reward; they point out, however, that "it requires a large difference in motivation to produce a relatively small difference in efficiency of performance." Delayed response experiments with chimpanzees have shown (1) that the accuracy of performance at a fixed delay interval is markedly greater with large than with small incentives of the same kind, (2) that the "limits of delay" (longest delays possible before accuracy falls below 75 per cent) are considerably higher when large rather than small rewards are used, and (3) that accuracy of performance is affected not only by the size of incentive and length of delay in any given trial but also by the reward-delay relationships obtaining in previous trials.

Token rewards. The work of Wolfe and of Cowles shows that chimpanzees perform almost as well in physical work and discrimination learning situations when correct responses are

rewarded with tokens (poker chips) which later can be exchanged in a slot machine for food, as when they are rewarded with the food directly. Some learning problems were mastered within a single session (of 20 trials), which means that the problem was solved without any primary reward, opportunity for "cashing in" the tokens not being given until the end of a session. The tokens lost their efficacy when opportunity to trade them for a desired object (food) or activity was withdrawn. The incentive-value of each token decreases as the animal's stock of such tokens increases. "In social situations the tokens elicited competitive behavior similar to that evoked by food" (Wolfe). On the basis of size, weight, texture and color differences the chimpanzees differentiated between tokens of differing values and chose water-tokens when thirsty, food-tokens when hungry.

Emotionality. In our Western civilization expression of the emotions is inhibited, suppressed, or repressed so effectively, sometimes, that it requires a long psychoanalysis for the individual himself to become aware of his feelings. It may be doubted that the infrahuman primate has many emotions hidden away in the unconscious. Nor is this because of a paucity of emotional responsiveness. The chimpanzee is emotional about many things, at frequent intervals, and expresses those emotions freely and promptly. In respect to no other aspect of behavior is this ape so almost human, so much a caricature of man. Implied here is the assumption that we can recognize emotions in animals and that we have the scientific right to apply to them terms deriving from human behavior and having, often, a decidedly mentalistic flavor. This problem cannot be discussed here. Hebb recently has presented cogent arguments for the logical justification, necessity, and scientific fruitfulness of resolving our confusion of the behavioral and mentalistic aspects of terms used in this field. As he points out, the fact that to us the state of awareness involved in "anger" or "fear" seems to be the critical element, does not vitiate the further fact that under certain circumstances others can recognize our "anger" with accuracy even when "verbal behavior" is not involved. The process of emotion-naming in ape and man utilizes similar behavioral indicators. With the highly expressive chimpanzee such recognition is often facilitated.

The forms of emotional expressivity vary considerably from species to species, from individual to individual, and in the same individual at different ages. In an experimental study in which food-reward for a certain performance was withheld or reduced in quantity on some trials, Finch has shown that young chimpanzees not only have a lower threshold for frustration (a higher frequency of frustration-responses) than adults, but also that their reactions are more violent and explosive in character. One youngster typically resorted to thumb-sucking when frustrated, but most of the younger subjects tended to have temper tantrums, scream, defecate and act aggressively toward themselves, the experimenter, or the animal in the adjacent cage. The older animals were more likely to turn attention away from the experiment, to scratch or groom themselves, or to go to the fountain for a drink of water.

Not much more than a beginning has been made in the definition or determination of "the adequate stimulus" for the various emotions. As in man, emotion appears mostly in social situations. There is no evidence that the infra-human primate "personifies" the inanimate environment. Even when the chimpanzee violently attacks and destroys the problem-apparatus which has proven too difficult, his anger seems clearly directed at the experimenter; such behavior, for instance, is not exhibited towards the water faucet when it suddenly fails to provide water. Once the terminological and epistemological difficulties which have beset this field are cleared away, progress in the investigation of emotion through primate research should be rapid and fruitful.

Individual differences; psychopathology. The range of behavioral variability within a given species of primates is impressively wide. In addition to age and sex differences mentioned under various topics of this article, individual variations in respect to intelligence, drive, emotional threshold, and so on seem to be as great as in man. In a large colony of chimpanzees there are as many "personalities" as there are individuals. Rating scales applied to a group of chimpanzees give a unique "profile" for each animal (Crawford). Differences of temperament are particularly obvious and dramatic but no more important, in research, than the intellectual deviations separating the "genius" from the "imbecile."

Attempts to produce "experimental neuroses" in the primates have been few and thus far have yielded no particularly important results. There are a number of extremely interesting observations of spontaneous (i.e., unintentionally produced) aberrations of behavior. Thus Tinklepaugh has reported the self-mutilation of a male rhesus monkey in a certain sexual-social situation. An adult female chimpanzee showed fear of food in large pieces (much less fear when the food was cut into small bits) over a period of years. Several chimpanzee females have manifested a marked and persistent depression of mood during the years of adolescence. Some of the anomalies of sexual behavior described above would, in man, be designated as pathological. Epileptoid fits have been observed in two infant chimpanzees, and Kopeloff has induced permanent susceptibility to epileptic fits in monkeys by placing certain substances in contact with the motor cortex. The combination of extreme dependence plus sadistic-bullying behavior observed in a young chimpanzee closely parallels the clinical syndrome of one type of "problem child." Inasmuch as the neuroses and psychoses are to a very large extent described in terms of symptoms pertaining to verbal behavior, typical examples of these classical syndromes will not be found among the primates; in view of the limited integrative span and absence of a highly organized symbolic system in these animals (see below) it may be doubted that they are capable of anxieties, paranoid systematizations, and so on, of the intensity and complexity manifested by man. It does seem probable, however, that the basic processes leading to such elaborations may be exhibited in the simpler behavior aberrations of monkeys and apes.

INTELLIGENCE

In any particular activity the organism behaves as a unified whole, with little or no regard for man's abstract analysis of functions, processes, or mechanisms. Only in rare instances, therefore, is it possible to discuss a bit of behavior in terms of a single psychological category and without reference to many other pertinent aspects of behavior. It must be borne in mind, consequently, that in each of the following divisions there is implicit if not explicit reference to topics treated earlier or subsequently.

I. LEARNING AND MEMORY

Learning is an alteration of behavior caused primarily by previous stimulation and response. Memory or retention is the persistence of such alteration. If there is any indication of learning, there is, therein, indication of memory, since the fact of alteration can be determined only by comparison of past and present performances. This inseparableness of learning-retention is especially clear in those experiments in which change ("improvement") is gradual, being measured, for instance, in terms of frequency or probability of correct response. If there is a 50 per cent chance of correct response on the first trial and a 95 per cent chance or frequency on the tenth trial this difference must be the joint product of learning (change due to previous stimulation-response) and of retention (persistence of the change). Most "memory" experiments, however, deal with the longer periods of persistence intervening between the (relative) perfection of a habit or acquired mode of response and a retention test given days, weeks, months, or years later. Obviously one cannot speak of memory in the case of an innately given S-R connection (e.g., a reflex); to speak here of "racial memory" is to point out a superficial, teleological analogy of questionable usefulness.

Memory. As seems to be true of all organisms, including man, "motor memory"—the retention of behavior alterations involving chiefly the acquisition of skills and patterns of motor response, as contrasted to those in which sensory or perceptual discrimination is the critical factor—is relatively excellent among the apes and monkeys. Thus tricks, such as handclapping, everting the lower lip or doing a pirouette (used to solicit food from the human audience), operating a drinking faucet, unfastening hooks, snaps, and padlocks, riding a bicycle, and stage or circus routines, are remembered over long periods of time. Although completely reliable evidence on this point is difficult to obtain, observations suggest that the gorilla and chimpanzee recognize people after absences of a year or longer. There is evidence that thoroughly practiced discrimination habits may be remembered—in the sense of giving initial above-chance scores and being quickly relearned to perfection—over a period of several years.

The most used method for testing memory capacity in the primates is that of the spatial delayed response. Typically the subject sees food being put into one (or several) of two (or more) containers, is removed from the situation (usually by the lowering of an opaque screen), and later is allowed to choose between the containers. Difficulty of the task may be varied by increasing its complexity or the delay interval. In general, the experimental results (Harlow and collaborators, Tinklepaugh, Yerkes) indicate that the anthropoid apes are somewhat superior to monkeys and are not markedly inferior to human subjects. In such comparisons there is always a question regarding the comparability of conditions for the different species being tested, especially in respect to motivation. In working with chimpanzees one gains the impression that with sufficiently strong motivation the delay interval could be extended almost indefinitely.

Discrimination learning. Many experiments have been performed in which primates are required to respond consistently to one of two stimulus-objects, avoiding the other one. Most studies of sensory limens utilize this method. The results in general (there are a few notable exceptions) indicate that primates are rather slow in forming such discrimination habits, not infrequently requiring up to several hundred trials to establish one such habit. Usually choice of the correct object is rewarded (with food) while choice of the incorrect object is unrewarded. Use of punishment for the wrong response has been tried but has not often been found helpful; if at all severe it may result in refusal to work or may interfere with (distract from) response to the critical stimulus. Various factors seem to contribute to this inefficiency of discrimination learning: 1. The prepotency of spatial factors over the cue as determined by the experimenter is suggested by the fact that position habits or spatial patterns of response are manifest during much of the learning period. 2. Fear of the experimental situation may be seen especially in "unsophisticated" subjects and would obviously reduce the efficiency of learning, as would any other distraction. 3. Any spatio-temporal features of the situation which reduce the togetherness or "belongingness" of the response and its consequence reduces learning efficiency. It has been shown that moving the critical stimulus a few inches

back from the place of response (pushing with the finger tips) may increase difficulty of the task enormously. 4. Over- or under-motivation (too much or too little hunger) will attenuate learning efficiency. 5. The chimpanzee sometimes appears to "get his wires crossed," responding consistently to the negative or unrewarded stimulus-object. These factors are discussed further, below, in connection with "integration."

Chimpanzees and some of the monkeys have a relatively small "frustration tolerance" in this type of experiment. If they fail in several successive trials, they may become excited and refuse to continue work. For this reason it has been found advisable to allow correction, in case of error, so that a reward is received on each trial. A brief delay after error, before allowing correction, usually provides sufficient "punishment."

The nature of the stimulus on which the discrimination is based has been investigated extensively, especially by Klüver, using "the method of equivalent stimuli" with monkeys. In such studies the usual procedure is to train the animal until a given discrimination habit has been mastered, and then to vary the stimulus-objects, noting whether the new pairs are equivalent, in the response evoked, or not. The general finding has been that often rather large differences can be introduced without destroying equivalence but that sometimes small changes completely disrupt the consistency of response. A large proportion of the data suggests that primates respond relationally: having learned to choose the larger or the heavier of two objects, they tend to select the larger or heavier of other pairs, differing from the original training pair in absolute values.

Spence has advanced a theory of discrimination learning by which many phenomena, including the apparent response to relations, are explained by the assumption of additive increments of excitatory strength (positive valence) being produced by each reinforced response, whereas increments of inhibitory strength (negative valence) are additively cumulated by unreinforced (non-rewarded) responses. Experimental data have been adduced in support of this theory, which has the great advantages (1) of having quantitative implications which can be put to test, and (2) of offering the possibility of a single, unified explanation for di-

verse phenomena. Its main weakness lies in the fact that, more often than not, the experimenter does not know to which of the potential stimuli in the situation the animal subject is responding; lacking that information, it is impossible to assign the calculated excitatory and inhibitory strengths to any particular stimulus and so to predict what response will occur in subsequent test situations. On theoretical as well as experimental grounds it may be argued that all stimuli are relational in character. Whether chimpanzees respond to that one of two boxes which bears a constant spatial relationship to the other one or which occupies a given "absolute" position, depends on the distance between the boxes; the former occurs if the distance is small, the latter if the distance is greater. Response to so-called "absolute" position, however, is probably response to a position which is relative to background features rather than to the other food box.

The C.R. method of discrimination learning, in which the subject responds to the presence, and refrains from responding to the absence, of a given stimulus (instead of responding positively in each trial to one of two or more stimulus-objects) has been used infrequently with primate subjects. Monkeys have been trained successfully to pull open a door only when certain auditory stimuli occurred (Wendt), and chimpanzees have learned to press down on a telegraph key whenever a tone was sounded (Elder). Eyelid responses have been conditioned in monkeys (Hilgard and Marquis). In all these studies learning was fairly slow and rather similar in its characteristics to that of lower mammals.

Maze learning. Maze experiments, comparable to those conducted with rats in which the animal runs through a series of alleyways, present technical difficulties with the physically larger primates. Only one such study is reported: that of Kinnaman in which two rhesus monkeys required 66 and 113 trials, respectively, to learn a modified Hampton Court pattern. These scores are not significantly different than would be made by rats.

Spragg used stylus mazes with young seeing and blindfolded chimpanzees. The subjects were required to push a stylus manually through a series of channels avoiding those which were blocked by hidden stops. The results show a strong tendency to anticipate the final direction

of response and a lesser tendency to persevere in the opposite direction of the earlier turns. In the balance of these opposing tendencies, the chimpanzees approximated human behavior more than that of rats. A similar anticipation of the final, reward-getting response was gradually eliminated when a chimpanzee had to push in three pegs and pull out the fourth. Following bilateral extirpation of the frontal areas, the tendency to anticipate the pulling response reasserted itself more strongly than before (Jacobsen, Wolfe, and Jackson).

2. LEARNING AND PERCEPTION

In the learning experiments described above the subjects were confronted by a "blind" situation. There is no way—unless it be mind-reading!—that the animal can know beforehand the consequences of its alternative responses: whether the experimenter has decided to reward response to triangle or to circle, to black or white, whether this or that pathway is blocked. In such a situation all that any organism can do is to try out the possibilities, to use the method of trial and error. As indicated above, the infrahuman primates do not appear markedly superior to the lower mammals in the application of this method. By contrast, man apparently can make better use of his initial successes and failures and so can attain the solution to a "blind" situation more rapidly. The principal exception to this rule is when the cue, the differentiating stimulus, is strictly positional, in which case the performance of monkeys and apes approximates that of man.

Human behavior is characterized by immediately adaptive response to a great variety of situations, many of which may be quite novel in the sense that their details vary from any situation previously experienced. They are not "blind" however in the arbitrary way of a maze, which may be of any conceivable pattern. They are, instead, situations which allow one to "see" the solution: a wire fence in front of the goal must be circumvented to get to the goal. They permit "insight"—they do not (typically) require overt trial and error. If the efficiency of blind learning distinguishes man to only a modest extent from the rest of the animal kingdom, the frequency and range of insightful problem solutions sets him far apart. The bases for such immediate solution have not been thoroughly analyzed. Certainly they

are many rather than one. A satisfactory description, categorizing, and ordering of the mechanisms or processes involved is the fundamental problem of intelligence—human and comparative. We may suppose that differences in innate perceptual organization, in the ability to abstract and to integrate past and present elements of experience (see below), and in the availability of a highly organized symbolic system, are among the factors involved. Starting with Hobhouse, followed by Köhler, Yerkes and many others, a variety of problem situations have been devised to test this capacity for immediate "understanding." (In the attempt to control for obvious differences in experience, particularly with certain types of materials, considerable ingenuity has been displayed in devising situations which would be "fair" to the organisms being tested. Quite often, when a problem was not solved by insight, it was used as a learning situation; certain types of problem boxes, for instance, illustrate such diversion from the original aim.)

Problem boxes. The name "problem box" has been applied to such diverse situations as a lever whose depression for no reason understandable to the animal subject results in delivery of a bit of food, to those in which the animal has merely to remove a lid in order to get at the reward. What is usually measured in problem-box experiments is the animal's persistence, variety of trial responses, how well it profits from successive experiences and successes, and finally the "transfer effects" from one problem box to similar ones, particularly the ability of the subject to respond on the basis of a mechanical principle, such as that of the lever. The Jenkins problem box is designed especially to investigate learning; three discs must be stepped on in patterns becoming increasingly lengthy and complex. The "limits of capacity" in terms of the average number of steps learned are scored as follows: cebus monkey, 9.8; rhesus monkey, 7.4; kitten, 3.6; rat, 0.9; guinea pig, 0.5 (Koch, Fjeld, Shuey, Riess). If the learning of a principle is involved here, it is merely that pressing down the circular discs has something to do with attainment of reward. Because of manual dexterity and freedom of the hands from the function of supporting the body, the primates are more successful than other animals in coping with various types of opening devices (Hobhouse, Köhler, Yerkes, Thorndike, Kinna-

man, Kohts). In general they improve with practice and from one problem to the next. How much such transfer is the result of grasping a principle and how much of reduced fear, greater attention to certain features, and so on, is rarely clear.

String tests. In the patterned string test the subject is first trained to pull in a string, to the further end of which a lure is attached. The animal is then confronted with a series of situations in each of which there are usually two strings, one with food attached and one or more without food. The strings are laid out on a platform in various patterns, the correct and incorrect strings being more or less easily distinguishable. Visual acuity obviously is a factor in the performance, as are impetuosity *versus* deliberateness of choice and attention to visual details; whether any "higher" functions are tapped by this test is open to question. It appears that chimpanzees may be slightly superior to monkeys in patterned string problems and that the former profit more by practice. One study suggests that spider and cebus monkeys are a little better than rhesus monkeys. That all tested infrahuman primates show considerably less accuracy in this test than man, and are superior to all infraprimates animals, seems unquestionable.

Use of sticks. Just what constitutes the critical difference, psychologically, between the ability to draw in a string, stick, or board to which the lure is attached, and the ability to use a stick as an extension of the arm to rake or sweep in an unattached piece of food, is not clear. The former task is solved quite readily by monkeys and apes, while the latter involves considerable difficulty and usually is solved only after much random activity with initial success being "accidental." Observations in the field indicate that chimpanzees pull or bend branches and twigs so as to bring the attached fruit within reach of mouth or hands; this would be analogous to the string-pulling experiment. Nothing has been reported indicating that the wild chimpanzee uses detached sticks in purposeful, instrumental ways. Serious fighting, for instance, is done directly with teeth and limbs; the use of clubs in combat has not been reported. Jackson and Birch have shown that young chimpanzees improve in their adaptive use of sticks after opportunity to play with them in non-goal-attaining activities. One of six

young chimpanzees living in an enclosure containing several trees, spontaneously (i.e., without human tuition or encouragement) developed a high degree of skill in using broken off branches, poking them through the wire of the enclosure to open door fastenings, to operate an electric light switch, and even to screw an electric bulb off and on in its socket. Needless to say, this animal gave an outstanding performance in formal tests of stick-using ability. The evidence in general indicates that experience plays an important role in developing the instrumental use of sticks and that the critical perception of the stick as a possible extension of the arm is built up gradually rather than being given in the innate organization of the visuomotor field. The demonstration that experience is an important factor here does not in itself invalidate the use of "insight" in accounting for the total behavior—it merely reduces the scope assigned to the insightful process. Once the animal has used a stick in attaining a goal, there seems to be considerable transfer to other objects and other situations. That is, if a stick is not available, a newspaper, wire, or even a bundle of straw may be used in place of it; a stick formerly used to open a door fastening will be used quite readily to sweep in a piece of food.

The meager data available suggest that certain monkeys (e.g., cebus) are better in stick using than others (e.g., Java and spider monkeys). Present information suggests that the limits of training may be higher for chimpanzees than for the other anthropoid apes and monkeys.

Complicated stick problems. The problem of obtaining food by use of a stick may be complicated in various ways. By placing low barriers between the lure and the animal, the subject may be forced to move the food laterally, or directly away from itself, before the lure is free of the obstruction and ready to be swept in. These indirections (Umwege), especially the latter form, present much difficulty to primates. Chimpanzees appear to be superior to monkeys in this problem. Observation of chimpanzee behavior in this situation suggests that the difficulty may arise not so much from perceptual failure—that is failure to "see" the correct or only possible pathway—as from an overwhelming compulsion to bring closer, rather than push away, a desired object. A sec-

ond complication is to have the stick out of the immediate situation; it is available but not actually in sight when the lure is in sight. Here one of the elements critical for the perceptual organization must be supplied by memory, memory of the stick previously seen but not present to the senses at the locus of the necessary final response. There is good evidence that, after ample familiarity with the several components involved, the chimpanzee is able to draw such a "mental" item into functional contact or unity with the immediately present situation, thus attaining what some authors would term a "reorganization of the psychological field." A third type of complication is to have immediately available only a short stick too short to reach the lure (Köhler, Guillaume and Meyerson). With the short stick, however, the animal can draw in a longer one, with which it can reach the food. The series, of course, can be extended to three, four, or more successively longer sticks. This problem has been solved by chimpanzees and by a cebus monkey. Usually the adaptive sequence of drawing in the long stick with the short one and then using the former to get the lure is preceded by unsuccessful attempts to use the immediately available short stick for reaching the food. The difficulty of this problem for chimpanzees is increased if the lure and all the necessary sticks are not together where they can be viewed simultaneously; that is, if at least one of the sticks is located at a distance from the lure. Under these circumstances the normal animal succeeds, whereas the chimpanzee with bilateral extirpation of the frontal lobes of the cortex fails utterly (Jacobsen, Wolfe, and Jackson). This finding supports other evidence regarding the function of these cortical areas; they appear to be necessary in integrating an item present only in memory with the immediate situation.

The tube and stick problem presents something of the same conflict of reaction tendencies as does the pushing away of the lure in order to get it free of a barrier. Here the lure is placed inside of a fairly long opaque or transparent tube (made of wood, pipe, glass, or wire netting) which is too small in diameter, or too long, to permit the animal to reach in with hand and arm. A stick is available, the problem being to use it to push the food out of the tube. This problem is extremely difficult for

monkeys and apes; those successes reported usually occurred only after extensive training.

Suspended lure and 'box stacking. As in the case of stick using, no behavior analogous to box stacking has been reported for the wild chimpanzee. Climbing or stepping up in order to reach overhanging food is common enough and requires no special training beyond that afforded any active animal in a native or usual laboratory environment. Pushing around unattached objects, such as boxes, chairs, or tables also is a "natural" activity. Thus it is not surprising that the suspended lure problem, which requires that a box or stool be placed under the point of suspension so that it can be climbed and the lure be reached, is solved fairly readily by chimpanzees and some monkeys. According to report, a certain amount of "random" activity with the box or stool usually precedes solution. Chance alone, however, does not seem to be responsible for getting the box in the correct position; quite suddenly, often, the box is pushed directly to the correct spot. Given certain elements: the lure suspended out of reach, the experience of climbing upon a box to reach such a lure, and the presence of a box or stool known to be moveable, a perceptual integration of these elements, a "structuring of the field," occurs by which the pathway to the goal, with the placement of the box under the lure as the first step, is perceived.

A similar, sudden perceptual organization occurred in a suspended lure situation described by Yerkes. "Two boxes were available, neither box alone giving enough height to reach the food. The subject was Soda, a seven-year-old chimpanzee. For the first forty minutes she made no detectable progress toward solution. . . . she now pushed the larger of the two boxes nearly under the banana, and going to the other box, which was near by, jumped from it toward the banana repeatedly but without success. Then she leaned for a moment against one corner of the experiment room, looking toward the banana. The larger of the two boxes was still almost directly under the banana and the smaller only a few feet away. Suddenly Soda stood up, walked directly to the smaller box, lifted it in her hands, placed it upon the larger box, and mounting the structure jumped toward the lure, reached and secured it. It was only a few seconds from the

moment she started toward the smaller box until she had the banana."

Numerous instances of successful box stacking have been reported for chimpanzees, with as many as four boxes being used (Köhler, Yerkes, Bingham). The gorilla and orang appear somewhat less adept in this performance (Yerkes). There has been only one report (Bierens de Haan) of success in box stacking with the lower primates, a cebus monkey being the subject in this case.

Other instrumental problems; tool-making. A variety of other instrumental problems, some of them highly ingenious (the hooked-rope problem, Bingham's channel apparatus, and many others), which have been set for primates, show essentially the same type of ability already illustrated or are somewhat difficult to analyze in terms of the psychological functions involved.

Just what constitutes tool-fabrication is obscure. Liberally interpreted, it might well include the use of boxes and sticks as already described, or in pole vaulting and pole climbing. Perhaps it should refer to performances such as the breaking off of a branch of a tree or the freeing of an iron bar, as described by Köhler for chimpanzees, in order to obtain an instrument for further purposes. The nearest thing to the manufacture of tools in the ordinary sense seen in primates is the observation reported by Köhler of a chimpanzee fitting together two short sticks in order to make a long one. This observation has not been repeated.

Imitation. The problem of imitation has long attracted the interest of students of primate behavior. Imitation is of obviously great importance in human learning and superficial observation, at least, suggests that it plays an influential role among the lower primates, as attested by our verb "to ape." Uncertainty as to just what constitutes "imitation" and the fact that the term has meant different things to different writers are responsible, at least in part, for the divergencies in results reported by the early investigators, most of whom used monkeys in their experiments. Warden and Jackson proposed five criteria for "imitation" and devised a special apparatus by which they could be met. Many of their tests gave positive results, indicating the capacity for imitation in rhesus monkeys. Elaborating the viewpoint of Watson,

Spence points out that even these findings may be interpreted as reflecting merely an "enhancement of the stimulus." More recently Crawford and Spence experimented with chimpanzees on the possibility of imitational learning of discrimination problems in which "enhancement" was eliminated as a critical factor. Positive results were obtained (1) in 5 out of 8 cases when the situation forced or encouraged the imitator to orient differentially towards the correct stimulus, to which the demonstrator made a positive choice response, (2) in 2 out of 7 cases when the imitator's overt orientation, necessary to obtain a reward, was to a point midway between the positive and negative objects, and (3) in at least one out of 11 cases when the situation provided no reward and minimal encouragement for a differential orientation by the imitator. The latter results provide good evidence for imitation, rigidly defined, in chimpanzees. The authors' suggestion that "the eating of food by the demonstrator may have served as a *substitute reward* for the imitator" may be questioned. To those well acquainted with chimpanzee behavior the experimental evidence for imitation is not surprising. The following is only one of several similar observations that might be cited. In the course of routine care the chimpanzees at the Yerkes Laboratories have ample opportunity to see the men using a key to open padlocks and door locks. On one occasion an adult female took a bunch of keys out of the coat pocket of an attendant while he was in her cage. The animal at once selected a key and rather awkwardly tried to insert it in the keyhole of a window grille. It was the wrong key. Efforts to get the keys back from her met with a gentle but firm refusal. She next applied the correct key to the door lock. After half an hour of exploration outside, her interest in the keys was diverted and she was lured back into her cage. It is almost certain that this animal had not had previous experience in the use of keys.

3. ABSTRACTION AND INTEGRATION

Generalization and abstraction. Having learned to respond in a given way to one situation (key depression with a certain tone; choice of the larger of two white boxes), an ape or monkey will make equivalent responses in certain other similar situations (key depression to tones varying from the original in pitch,

loudness, purity; choice of the larger of two black boxes or of two boxes differing in absolute size from the training pair). Such phenomena are usually called "generalization." With sufficient training, chimpanzees will come to respond consistently to a given form under a great variety of circumstances, including changes in background, in rotation and size of the figure, and in the characteristics of the alternative with which it is paired. Such a performance is often termed "abstraction." The difference between generalization and abstraction as thus illustrated is obviously one of degree rather than of kind, the latter being more difficult. The reasons for the difference in difficulty may be analyzed into three factors: (1) The greater the difference in the context in which the cue or critical stimulus appears, the greater or more likely will be the disruption of the response. The more the antecedent (situation) varies from the original, the greater the probability of the consequent (response) varying, to use Hollingworth's terminology. The effects of the parts of a situation are, roughly, additive. (2) Partly because of experience but mostly because of genetic constitution, different stimuli are more or less obvious, obtrusive, and compelling for any given organism. As Klüver has pointed out, what is obtrusive for one species may be most obscure for another; two stimulus-objects lie on a given dimension for one animal but may not be on that same dimension at all for another organism. For all primates, for instance, there appears to be a visual size dimension, but such dimensions as number, triangularity, and middleness are difficult, obscure, or even non-existent for most. Many dimensions or groupings of stimuli, as a matter of fact, seem to be impossible without a language or language-like system of symbolic processes. (3) Even in a simple two-choice situation there are usually many differences, rather than one, between the alternatives: in the case of two white squares differing in size, there is difference in total illumination, in area, in horizontal length, vertical length, length of the diagonals, and, usually, in nearness of the edges to fixed landmarks of the background. The animal subject may solve the problem by responding to any one of these—it doesn't know which of these features the experimenter may be thinking of in devising subsequent tests. Thus there is a premium on attention (response) to all differ-

ential features; the more inclusive the response, the more likely will be "positive results" in the tests for abstraction.

Multiple choice. In the multiple choice method of Yerkes the correct response is to that one of several boxes, or compartments, identical in appearance, which bears a constant spatial relationship to the others. Thus the positive box may be the left-hand one of a variable number, or the middle one of 3, 5, 7, or 9 boxes whose absolute position in space varies from trial to trial. The former, end-box problem, is learned readily—more quickly, as a matter of fact, by the pig and crow than by various primates. Especially in the apparatus used, which accentuates the position of the alternatives to each other rather than to a background feature, the stimulus, "left-end box," is apparently an obtrusive one to which the animals respond easily and naturally. The stimulus "middle box," by way of contrast, is not obvious to animals below man and presents great difficulty. With the original technique of varying the number of boxes from trial to trial, four chimpanzees as well as a monkey and two pigs failed in this problem. By keeping the number of boxes constant at five, and using only four different settings of 11 boxes, Spence obtained solutions of the middle box problem in all of 17 chimpanzee subjects, very young animals learning about as readily as adults. The technique of using a constant number of boxes makes this problem easier (1) by reducing the contextual differences in the situation and (2) by reducing the number of possible cues to which the subject might respond and from among which the correct one must be selected. In the analysis of his data Spence indicates the probability that five of the chimpanzees "adopted a generalized mode of solution" whereas the other twelve "learned each specific setting of boxes separately." This may be interpreted as meaning that the latter subjects perhaps never did respond to the cue "middle box" but may have responded, for instance, to each of four "absolute" positions depending on the context (setting) used.

Figure-ground; oddity. Novel objects, insofar as they do not inspire fear, are closely and minutely examined by monkey and ape. Observation reveals that it is the irregularities in the object that receive the closest inspection: cracks or spots on the wall, small blemishes on the

skin, the seam on a rubber ball. It is the figure, and not the homogeneous background, which gets attention. The natural response to what is different is exploited in the discrimination method variously called "strata stimuli," "unequilibrated" or "non-equated stimulus situations," and "oddy method." If response to oddity were completely prepotent over response to other stimulus dimensions, it would be possible to test the entire range of discriminative capacity of an animal in a relatively short time and without the usual laborious procedure of training required by the conventional techniques. A comparison of the "equated" (one positive and one negative stimulus-object) and the "non-equated" (one positive and 9 or 11 similar negative stimulus-objects) methods, as used with chimpanzee subjects, showed that although there is an initial propensity to select the odd (positive) object, this is not completely prepotent over other response tendencies. From the beginning, however, the non-equated situation is more efficient, presumably because the natural response to oddity augments the effects of the arbitrary rewarding of that object having certain properties, specific and relative to those of the "negative" objects. It is interesting to note that oddity was more effective with intrinsically more discriminable objects (colors) than with less easily discriminated objects (patterns). That response to features other than oddity was strengthened by training is shown by the negative transfer manifested when positive-negative values of the stimuli were reversed. Such negative transfer, however, was reduced almost to zero when reversal occurred by or with the technique other than that used in the original training. That is, with a marked change in context past learning was less effective and change to another basis of response (e.g., from specific properties to oddity) was easier. As these chimpanzees were trained in a series of discriminations with the non-equated method, they came to respond more and more to the feature common to all the problems: the oddity of the positive stimulus-object. The training necessary for evidence of discrimination therefore became progressively shorter. It was found, however, that after the subjects responded immediately to the odd color of any color combination they did not at once select the odd pattern of various pattern combinations. The oddity method has been applied with great

success by Harlow and his associates in an extensive series of experiments with monkeys.

The matching method. The matching-from-sample method also offers the possibility of a short cut in testing for discriminative capacity but seems to require much more preliminary training than does the oddity method. The task of the subject is to select that one of two or more objects which is like the sample presented. The stimulus, "similarity-to-sample," is not one to which primates respond naturally, as they do to a figure-on-ground or what-is-different. It is clear, however, that once response to this stimulus has been established, tests of discriminative capacity may be conducted quickly and efficiently. Kohts obtained much information about her chimpanzee subject with the matching method and the Wisconsin group of comparative psychologists have used it extensively and fruitfully with monkeys. Weinstein has employed it as a sorting or "color categorization" method, having the monkey subjects respond to several objects matching the sample in hue (but differing in size, shape, brightness and saturation) while refraining from response to other objects differing in hue from the sample. This is an excellent example of abstraction as defined above. By maintaining a constant shape for the color-samples (triangle-red, ellipse-blue) over a long training period, this investigator succeeded in getting one monkey to pick out only red objects when the sample was an uncolored triangle, blue objects when the sample was a colorless ellipse. "The color categorizing performances indicate that in the course of training the subjects developed concept behavior towards red and blue objects." Conversely, the subject selected the achromatic triangle or ellipse when the sample object (of various shapes) was red or blue. "Since this stimulus-response pattern is the converse of selecting a colored object in response to a symbolic cue it is termed *converse symbolic behavior*."

Integrative span. It has been indicated above that an animal's range and flexibility of attention (number of elements to which response is made) influences its success in abstraction. Many life situations put a premium on the organism's ability to respond *simultaneously* to a number of distinct features: A is edible if it is also B₁ and C₁ but not if it is B₁ and C₂. A

number of experimental problems illustrate this integrative capacity and suggest that species may differ widely in the complexity of the "if W and if also X and Y, then Z" function which they can attain. In one study young chimpanzees mastered the following set of two-choice problems:

- (1) If the squares are equally small, then the white one of the two is correct.
- (2) If the squares are equally large, then the black one of the two is correct.
- (3) If the squares are equally white, then the large one of the two is correct.
- (4) If the squares are equally black, then the small one of the two is correct.

Under very similar experimental conditions rhesus monkeys failed to solve both of the first two problems, a gibbon mastered the first two but was unable to add the third and fourth to the complex, while cebus monkeys were able to master three of the four (Galt). In a further study with an adult chimpanzee, a dozen interrelated habits were learned, the only difference between the two objects presented on a given trial being one of size. Whether the larger or smaller one was correct depended on its color (white or black), shape (square or triangle), patterning (whether or not it had a pink margin), and presence or absence of a small green peg in front of each object. Other than position (the positive object might be to the right or left), therefore, correctness depended on five cues—disregard of any one of these would lead to failure (50 per cent errors). The addition of the fifth necessary cue caused marked difficulty and, under the particular conditions of experimentation, may mark the limits of chimpanzee capacity. It is interesting to note that this animal did not respond to the generalized meaning of a given cue, as would be dictated by the interests of efficiency. In the first four habits, for instance, none of the objects had a margin. In these four problems the correct objects were: large white square, small black square, small white triangle, large black triangle. With margin added all these objects became of negative value (were unrewarded). But instead of learning the four new habits simultaneously, as might have been the case if the margin had been responded to as "reverse

of previous valence," each pair was learned separately.

Working with spider and cebus monkeys, Lashley presented a series of 25 discrimination problems and their reversals. The original habit always involved a plain background, the reversal a striated background. Before going on to a new pair, a criterion of 40 correct responses, with the stimuli appearing on plain and striated backgrounds in random order, was required. The monkeys never learned to respond promptly to the background-difference as a sign of reversed stimulus values when successively new discrimination-pairs were presented, although the spider monkey did get to the point of making a chance score (instead of 100 per cent wrong) when the background was changed from plain to striated on a newly learned pair of stimuli. In another unpublished study Lashley gave a spider monkey 116 discrimination problems, in each of which the correct stimulus-object contained two like figures (e.g., two squares) while the incorrect one was marked by two unlike figures (e.g., a square and a circle). Learning was quite rapid on all 116 problems, but no better at the end than at the beginning of the series. That is, the monkey did not abstract the cue-dimension of similarity-dissimilarity from the diverse contexts of the varying figures used.

Harlow and Spaet have reported studies indicating considerable ability on the part of their rhesus monkeys to integrate a number of elements. Their procedure is such that a direct comparison with the last-described chimpanzee experiment is not possible. The animals mastered the following set of habits, in each of which three objects were presented for choice:

- (1) With a yellow background the odd object (of two like and one unlike object) is correct.
- (2) With a black background the non-odd objects (of two like and one unlike object) are correct.
- (3) With a yellow background and 3 buttons available, the left-hand one is correct.
- (4) With a yellow background and 3 T's available, the right-hand one is correct.
- (5) With a black background and 3 buttons available, the right-hand one is correct.
- (6) With a black background and 3 T's available, the left-hand one is correct.

Considering the first two habits, it is clear that the subject must respond to background color and oddity. In the last four the subject must attend to background color, nature of the objects (electric push buttons *versus* T-shaped blocks), and position (rightness *versus* leftness). The question arises as to how many cues must be integrated when all six habits are mastered simultaneously. If we assume that the subjects approached the situation with a set (prepotent readiness) for responding to oddity *versus* non-oddity (as might be expected from the circumstance that they learned this first), then the mere fact that no oddity stimulus was present (in the last four problems) would be enough to eliminate this possibility and would make it unnecessary to respond to the pattern difference (2 of one kind, 1 of another *versus* 3 of a kind) as a cue. If this assumption is incorrect, Harlow and Spaet are right in considering configuration a fourth variable. At any rate it is clear that rhesus monkeys have a very considerable integrative span. In further work these investigators showed (1) that extirpation of the prefrontal cortex reduces this capacity in the rhesus, and (2) that two cues of different modality may determine response (choice of a T at sound of buzzer, of a push button at the sound of a bell).

Behavior plasticity. Various examples of both plasticity and inflexibility have already been noted incidentally. A few experiments have been designed especially to examine this aspect of behavior which, of course, is involved also in the above discussions of integrative span and the inclusiveness of response to the variety of potential stimuli in any situation. Hamilton tested human adults and children, monkeys and lower mammals with an insoluble problem, the subject being allowed to select one of four spatially differentiated possibilities. The only rule followed in determining correctness was that the same one of four doors was never correct on two successive trials. He found that man gave the highest, monkeys the second highest, proportion of "inferentially correct" responses: avoidance of the door which was open (correct) on the preceding trial. The number of possible cues which might designate the correct choice is relatively huge, and the problem is further complicated by the fact that a "correct" response involves one frustration on a third of the trials and two frustrations on another third;

rewarding occurs on the first attempt in only one-third of the trials guided by rational inference. The latter requires that the subject remember the open door of the last trial and respond to "something different."

Goldstein and others have stressed the significance of the ability to shift attention rapidly from one to another aspect of a situation in psychiatric and neurological patients. This ability has been tested in monkeys by the oddity and matching-from-sample methods (Harlow, Young, Simpson). Rhesus monkeys were successfully trained (1) to select that one object of three which was odd in respect to color when the objects were on an orange-colored board, and that one of the same three which was odd in respect to form when they were presented on a cream-colored board, (2) to select that object which matched the sample in respect to color when the sample was rewarded and to choose the one matching the sample in respect to form when the food-well under the sample was empty. The latter performance was possible even when a delay of 10 to 14 seconds intervened between contact with, and sight of, the sample and opportunity to respond to the choice objects.

4. TEMPORAL INTEGRATION

It is obvious that most if not all instances of intelligent behavior considered thus far involve the integration of past and present elements of experience. The present section deals with experiments (and theorizing) bearing more directly or analytically on the problems of temporal integration.

Double alternation. The double alternation problem has considerable theoretical interest since, according to Hunter's original analysis, its performance involves the use of representative factors or symbolic processes. The subject is required to respond twice to right, then twice to the left, and so on: R R L L R R . . . Since the external stimulating situation is the same after the first L-response as after the second, what cue can the animal use to make an L-response in the first instance, an R-response the next time? The assumption is that the differentiation is made through self-stimulation by a process analogous to counting. Gellermann found that rhesus monkeys could master the sequence: R R L L R R L L and could then extend the series to 12 to 16 responses. The

evidence for a symbolic process in this case is not too convincing, however, since the responses were made at a rapid and fairly uniform rate; there is other evidence that the effects of an S-R last or reverberate for several seconds (or longer), so the possibility exists that stimulation after the first L included after-effects from turning from R to L, whereas following the second L-response such after-effects had greatly diminished or disappeared.

"Counting"; the temporal maze. Several "counting" experiments with monkeys have been reported, a few of which claim positive results. The evidence that anything more than distance perception, response to moreness, or to secondary cues was involved in these studies, is questionable.

Spragg attempted to train young chimpanzees on a "temporal maze" using the response pattern, R R R L. As in double alternation, the external stimulating situations are exactly the same just before all but the first R responses and before the L response. After extended training two of the subjects were able to perform correctly (without any error) in some 31 to 48 per cent of the trials; most of the errors made were anticipations of the final L response.

Delayed reward. There is no evidence that any organism below the primates can form an association involving non-spatial cues if the consequences (actual, or signified as in delayed reaction) of the response follow it by more than a few seconds. Riesen, working with chimpanzees, found that his control subjects could not learn a red-green discrimination habit if rewarding (or non-rewarding) occurred more than 4 seconds after selection of one of the colors; delays as short as 1 or 2 seconds retarded learning markedly in comparison to the no-delay condition. The experimental subjects, however, who previously had been overtrained on a series of color discrimination problems requiring consistent choice of the longer of two wave lengths, learned the red (positive) *vs.* green (negative) and green (positive) *vs.* red (negative) habits much more quickly and performed equally well with reward-delays of 16 or 20 seconds as with shorter (including zero) delays. This finding is interpreted as indicating that a delayed reward can be effective in modifying behavior (producing learning) only if the subject has readily available, consistent responses which are differential in respect to the

critical stimuli (red-green). Otherwise "the cue is lost to the organism."

Delayed response. The delayed response problem is a special case of discrimination learning, with emphasis placed on retention rather than on acquisition of the behavior modification. It is a special case in that (1) learning takes place in one rather than in several trials, and (2) reinforcement of the learning is merely signified, the actual reward being given only after a successful learning-retention performance. Since many learning-retention units can be given in a short time, the method is an efficient approach to the study of factors affecting behavior modification. It provides, furthermore, certain unique possibilities for behavior analysis.

In the first place we have the striking fact that monkeys and apes manifest a very marked capacity for delayed response when the cue is spatial or positional but have great difficulty with the problem when the cues are non-spatial in character (*vide supra*). With chimpanzees it is initially almost an all-or-none difference. In a number of experiments, employing a variety of modifications of technique, chimpanzees have demonstrated their ability to do delayed response with non-spatial cues, but usually only after prolonged training and rarely at delay intervals over 30 seconds or with an accuracy greater than 80 or 90 per cent. Experiments reported from the Wisconsin laboratory indicate that rhesus monkeys performed in this task with an accuracy of around 85 per cent at delay intervals of 12 seconds. With both monkeys and chimpanzees an approach to delayed response has been made via a series of discrimination problems, with stimulus-objects changed or stimulus-values reversed, from one to the next; the number of errors before mastery tended to decrease with continued training, in some cases dropping to the theoretical limit of 0.5 errors per habit. This technique was more successful with the monkeys than with the apes, possibly because many different stimulus-object-pairs were used with the former, whereas only one pair, with stimulus-value reversals, was used with the chimpanzees, possibly because of the use of stereometric objects which the monkeys actually handled *versus* the use of planometric stimulus-objects which were merely pushed back by the chimpanzee subjects. Improvement shown by the monkeys was quite sudden: during the first five (difficult) problems the aver-

age error score was 24.3, dropping to an average of 0.97 on the next 36 (easier) problems. From one-trial learning—that is, mastery after a single rewarded or unrewarded experience—it is only a short step to delayed response, in which the designation of the correct alternative is indirect rather than direct.

The very marked difference in difficulty of discrimination learning and delayed response when spatial or non-spatial cues are involved may be one of degree: the spatial cue obviously has prepotency and, since any stimulus-object must appear somewhere in space, the subject may continue to respond to its spatial aspects to the exclusion of, say, its visual characteristics. Once the animal has "restructured" the situation—has focused its attention on the visual dimension—delayed response to non-spatial cues should become as easy as to spatial cues.

Another possibility, originally suggested by Hunter, is that quick (one-trial) learning involves a different mechanism or process than does slow discrimination learning. This might be similar to the symbolic process suggested above for learning with delayed reward, and would be diagrammed as follows:

At the beginning of the trial the successful subject makes its ready-made symbolic response to "RED" and this becomes associated with the forward-going (positive) tendency whose overt expression is, at this time, blocked by the external situation (vertical lines). Such an association is not formed with the green box, since this is not designated as containing food. At the end of the delay interval, the obstacle having been removed, the red stimulus sets off an associative chain leading to a positive response. According to this hypothesis the primates (and probably some of the lower mammals) have developed symbolic (implicit, differential) responses to spatial but not to non-positional cues. Some of the chimpanzee experiments lend plausibility to this formulation by showing, for instance, that animals who first have learned to make different movements in response to red and green (lifting a handle for red, depressing

a lever for green) subsequently are more successful in red-green delayed response than those who did not have prior training in making such differential movements.

The second feature which was listed above as distinguishing delayed response and certain types of so-called insightful (immediate) problem solutions from multi-trial learning situations is that in the former the subject does not actually obtain a reward until after the correct, errorless response has been made. That the kind and size of incentive employed affects the intensity and nature of the effort made to obtain it has been demonstrated experimentally. The term "expectancy-value of the incentive" has been used to designate the function of the lure in affecting behavior occurring before it has been obtained. A fairly specific expectancy is indicated by Tinklepaugh's observation that monkeys, accustomed to receiving a given kind of reward in delayed response trials, showed signs of frustration, disappointment, and searching behavior when a less preferred food was substituted. Still greater specificity of the expectancy aroused by the particular incentive used on a given trial is indicated by the fact that chimpanzees performed with greater accuracy on large-incentive than on small-incentive trials even when these were randomly alternated. The expectancy aroused by a certain lure or reward-sign must itself be reinforced or confirmed: when a medium-sized reward was always given for correct response, regardless of whether a large or small incentive had been shown at the beginning of the trial, the difference in accuracy of performance under the two conditions gradually disappeared. In some unpublished experiments with chimpanzees it was found that the incentive effects on accuracy scores could be reversed by consistently giving large rewards for correct response on small-lure trials, small rewards for correct response on large-lure trials. The fact that the animals can learn that a large incentive "means" a small reward implies that they integrated the two events (sight of a large piece of food, reception of a small piece) which were temporally separated by length of the delay interval, ranging up to two minutes and longer. Symbolic processes, that is, implicit responses differential for large and small incentives, would provide a possible mechanism for this temporal integration.

PHYLOGENETIC COMPARISONS AND EVALUATIONS

Details of phylogenetic relationships among the primates, and of the primates to other mammalian orders, are uncertain. Behavioral and physiological criteria, thus far given scant attention by the taxonomists, are not always consistent with morphological data but may prove extremely useful in tracing the course of primate evolution (Zuckerman). It seems probable that various groups of primates have followed separate lines of development from early times in the history of the order, but which of the extant forms are closest to the direct line of human descent is unknown. As to the relatively immediate future, man seems to hold the greatest promise of further advance. The specializations of the other primates (e.g., brachiation in the gibbon, large size in the gorilla) have the features of dead end stopping places, whereas man's large and "plastic" brain is perhaps less a specialization than a potentiality for further development along a new dimension of progression: a development which, instead of proceeding by germinal variation and mutation, progresses by the pyramiding of cultural accretions.

If we include man in our comparisons, the range of behavior variations within the order of primates is enormous. Even excluding man, the differences in intelligence from tarsier, lemur, and marmoset to the anthropoid apes are perhaps as great as those among all the other mammals together. Judged by our present knowledge, there are rather few significant behavioral advances from some of the marsupials and insectivores to the most primitive primates. This diversity in regard to many aspects of behavior within the order of primates deserves emphasis.

Man's upright posture together with his manual dexterity gives him a decided advantage over all other creatures in fashioning the environment to his needs. When this ability is directed by human intelligence in the fabrication of tools, machines, instruments, and materials, man's control of nature becomes almost incomparable with that of other members of the animal kingdom. What is "human intelligence" and how does it differ from infrahuman intelligence? Those two questions are inseparable, and the fact that the analysis of either one inevitably furthers our understanding of the other is basic

to the rationale of comparative psychology. Until analysis has defined the dimensions and the measuring units of intelligence, of mental evolution, differences can be stated only in crudely descriptive terms, in words referring more to "practical" end-results than to processes. Recognizing, and for the moment accepting, the incompleteness and imperfections of present psychological analysis, we may indicate certain broad differences and similarities which emerge from a comparison of the most highly developed infrahuman primates (the anthropoid apes and some of the monkeys) with man on the one hand and with some of the lower animals (especially the remaining mammals, birds, and insects) on the other:

The relative frequency of innately determined, uniform behavior sequences in adjustments of the organism to its environment is definitely less in the higher primates than in other animals, slightly greater than in man. What might superficially appear as the corollary of this, namely that learning plays a relatively greater part in day-to-day activity among the phylogenetically higher organisms, seems less certain. The most significant change is in the nature and diversity of what is learned. The speed of learning is greatest in man, but that it is usually greater in the monkeys and apes than in some of the lower animals has not been proven. Perceptual scope, the number and diversity of relationships which are or may become stimuli, is much wider than in the infra-primates, much more restricted than in man. In respect to inclusiveness or comprehensiveness of response to the various aspects of a situation, the higher primates again occupy a midway position. This is true also of integrative span, the ability to base a given response on a combination of factors (stimuli), and to bring past experience into relationship with the present situation.

It is reasonable enough to suppose that phylogenetic differences in emotional expression, in attitudes and goals, and in forms of social interaction, are the direct result of differences in intelligence or that both sets of variation are co-derived from a more basic alteration. The chimpanzee, for instance, seems to have all the primary emotions that we know in man, but his expression of those emotions is more simple and direct. His basic drives are the same as man's and he exhibits "functional autonomy of

motives" only to a lesser degree of complexity than does *homo sapiens*. His sensitivity to social stimuli is possibly greater than ours; the fact that he has not developed a highly organized society with specialization and division of labor, teamwork, and so on, may be ascribed to his intellectual equipment, his lack of a language for communication, and perhaps in part to the absence of an urgent, environmentally imposed necessity.

Man's behavioral superiority has two significant accompaniments: (1) an absolutely and relatively large brain, particularly in respect to the cerebral cortex, and (2) a highly complex, conventionalized system of symbolic processes (language). The former may well be the necessary basis for the latter and, directly or indirectly, for man's advantage in the several aspects or dimensions of intelligence outlined above. From this viewpoint psychoneurology, the investigation of the neural correlates (quantitative, topographical, and physiological) of behavior, assumes primary importance. Brain size and organization, and characteristics of neural functioning of course set definite limitations on the possibilities for behavioral development. It seems probable, however, that among the infra-human primates motivating conditions have not been such, either in racial history or in ontogeny, to bring these potentialities to their full expression. In captivity a high premium can be placed on the exploitation of intellectual capacity, but in any given instance this has been done only sporadically and never consistently and intensively over the critical years of early individual development. It is generally assumed that man's relatively long period of physical and mental growth from birth to maturity contributes importantly to his ultimate capacities. In the apes this period is almost as long and thus affords comparable opportunity for education and training.

If, in the above comparisons, we had chosen our representative of man from primitive societies rather than from modern Western civilization, the difference between human and infrahuman behavior would be appreciably lessened. Indeed, it might be questioned whether there is a greater behavioral advance from anthropoid ape to primitive man than from the latter to an Aristotle or Newton. If all the systematic and fortuitous extra-organic factors which, through the years and epochs, have

helped to bring about man's highest achievements were brought to bear on the monkeys and apes, the comparative picture might well be changed materially.

PRIMITIVE MENTALITY.—By title the subject matter of this article belongs in a field in which various groups of investigators are interested. Biologists and social anthropologists are concerned with the qualification "primitive," while the matter of differences in mentality would normally be enquired into by racial or social psychologists.

There is probably general agreement between physical anthropologists that mankind may be divided into groupings, the members of which resemble each other physically to such a degree that these divisions may be called "races." Hrdlicka (17), for example, states: "Human rasciation of the present is one of the plainest and most generalized evidences of continuing human evolution." In another publication (18) this same authority points out that this rasciation "is a universal biological manifestation . . . encountered in all animal species that have a wider distribution and larger numbers, and doubtless in all plants." He lists plasticity and variability of living organisms, environmental conditions, heredity, natural selection, hybridization, segregation, and possibly mutations as factors in the process.

Biologists give similar racial definitions. Jennings (19), for example, defines a race as "a set of individuals having many genes in common—in spite of many differences in genes among the component individuals—and differing in these common genes from other sets of individuals, other races." Jennings also points out the resemblance between the dog, in its differentiation into strains, or breeds, and man in his racial development. Both biologists and physical anthropologists agree that individuals within the racial division do not show all the distinctive features equally. There is considerable overlapping and this fact may help to account for disagreement as to the number of races that anthropologists distinguish.

In determining which characters are to be considered the marks of primitive physical development, we must take a brief backward glance into the story of the evolution of the brain. A most important index of primitiveness, both animal and human seems to be the development of the frontal lobes and particularly their prefrontal areas. The demonstration of progress from the simple reptilian brain, with nine-tenths of its substance devoted to smell, up to the cerebral equipment of modern man forms a fascinating chapter in comparative anatomy. From the highly developed smell brain of a long snouted primitive marsupial, such as *Dasyurus*, to its diminishing importance in the tree climbing marsupial, the Koala (*Phascogale*), and thence to its rudimentary appearance in the Red Monkey (*Cercopithecus*) and its almost complete lack of representation in

man, the smell brain falls as the frontal pallium rises in importance.¹

The story of protohuman and prehistoric frontal lobe development is continuous with that of the rest of the mammals. In the skull cap of *Pithecanthropus erectus*, unearthed by Dubois in Java in 1891, very little space is reserved for these important areas, the whole brain capacity being less than 1000 c.c. The fragmentary brain case of the Piltdown man (*Eoanthropus*) is according to Elliott Smith (35) markedly flattened in the frontal regions. The skull vault of *Sinanthropus*, or Peking man, discovered and described by Davidson Black (4), though a little higher and narrower than that of *Pithecanthropus* is similarly poorly developed in the frontal regions. Rhodesian man, described by Dart in South Africa, shows some progress in the height of the cranial vault, but is still very primitive. Coming nearer to modern times, Elliott Smith describes Neanderthal man as "an uncouth creature, with an enormous flattened head, very prominent eyebrow ridges, and a coarse face," to which he adds: "The large brain is singularly defective in the frontal region."

With regard to the aboriginal Australian, his skull is also distinguished by prominent supra-orbital ridges and low height in the frontal regions. His brain capacity is small, 1328 c.c. as determined by Porteus (31), 1347 by Burston. This figure may be compared with 1000 c.c. for Peking man and 1483 for the white Australian as determined by Berry and Porteus (3). With these and other comparisons in mind, Elliott Smith has no hesitation in stating: "The aboriginal Australian is the most primitive of existing peoples. He is to be regarded as the survivor of one of the lowest forms of the species *Homo sapiens*."

As to the Australian's racial classification, all anthropologists seem to agree in considering him as unique, differing from all other existing races of mankind. In skin color he resembles the Negroes; in stature, blood grouping, hair texture, hair distribution and cranial index, the Anglo-Saxon group, so that Hrdlicka declares that the aborigines' basic relations are with the white race. He regards them as "a derivative of the late glacial man of Western Asia, a remnant of an ancient stock." Boas (6) seems to be in agreement, for we find him stating: "The

¹ See Wood, Jones and Porteus (20).

Australians . . . exhibit a number of rather primitive features that set them off sharply from other races, and make us incline to the belief that they represent a type, differentiated at an early period, that may have been crowded back by the more successful races into remote corners of the world."

Thus, both because of his position among his contemporaries and his affinities with ancient races, there seems to be every justification for selecting the Australian as typical of primitive man, and centering much of our discussion about his mentality. An additional reason for so doing is the fact that there have been comparatively few studies of primitive folk elsewhere, only the more recent of which will be cited.

It should perhaps be emphasized, however, that though anthropologists may agree in placing the Australians near the bottom of the human evolutionary ladder, the aborigines do not exhibit in themselves all the physical characters that have been labelled "primitive." Indeed, the distribution of these characters is rather remarkable. Prominent brow ridges, for example, are typical of the Neanderthals, Rhodesian and Peking man, and the modern Australian, but they seem to be missing from among the Cromagnons and present-day Negroes. Moreover, they are by no means uncommon among whites. In skin color the Bushmen and the Australian aborigines, both primitive peoples, are very far apart, the former being brownish-yellow, the latter black. The Hottentots and Bushmen are also entirely dissimilar from the Australians in hair characteristics, their fuzzy peppercorns being quite the opposite to the wavy, profuse hairiness of the aborigines. None of these characteristics, therefore, can be regarded as unfailingly distinctive of primitiveness. All this amounts to the conclusion that the human family is extremely mixed and that even Nature seems to have had considerable difficulty in keeping the races straight. Admitting this confusion, there still is no justification for denying the reality and significance of racial differences.

Even brain capacity is not an infallible guide, though on the whole it is one of the most reliable indications. The Vedda of Ceylon (supposedly related to the Australians), according to Seligman (34) quoting the Sarasins, have

a capacity of 1278 c.c., while Boule (7) gives that of Andamanese Islanders as 1300 c.c. or 100 c.c. less than the average of four Neanderthals. On the other hand the brain capacity of Esquimaux is cited by Klineberg (22) as 1563 c.c. which is relatively large. However, Welcker, whom Klineberg is quoting, gives an entirely different figure, 1452 c.c., for Greenland Esquimaux, but as the number of skulls on which these averages are based is not given, the figures have little significance.

The question of the relationship between brain capacity and intelligence is by no means settled. Certainly the oft-quoted investigation on the subject by Karl Pearson (29) is not conclusive, since it has a very indirect bearing on the problem. He correlated two single measurements, length and breadth of the head, with an unstandardized mental measure, reducing results to a twelve year equivalent, and found two small positive correlations. Neither brain capacity nor intelligence can be judged on such inadequate data. Nor does anyone know how important from the standpoint of adaptability a small correlation between intelligence and brain capacity or any other correlated physical character may be, if constant over a number of generations. If one racial group had a slight but constant superiority in, say, strength of grip over another group, and this were correlated to any degree with intelligence the cumulative effect may be great in terms of motor efficiency and achievement. The differences in brain capacity between two racial groups may be equally significant.

One conclusion seems acceptable with regard to this matter. Taking the whole range of animal phyla, there would seem to be a correspondence between complexity of behavior and size and complexity of the brain. The details of the correspondence have not yet been worked out. The sciences of neurology and psychology are as yet in their infancy so that no one knows adequately the physical and physiological correlates of intelligence. The best neuroanatomist cannot take the brains of two individuals who had, respectively, I.Q.'s of 85 and 135, and point out the structural differences that would account for the admittedly great differences between the two in terms of social adaptability or learning capacity. The results of brain surgery² may

² See article on Prefrontal Lobotomy.

throw some much needed light on the problems of brain organization in relation to personality and intelligence.

As regards the physical characteristics of primitive people we are justified in making another observation which seems very significant. This is to the effect that the racial groups which differ most in physical characteristics from the whites are furthest removed from them in cultural advancement. If the two conditions have no causal connection, then it would be a most remarkable coincidence that Andamanese, Bushmen, Hottentots, Papuan, African and Asiatic negritos, Senoi, and Australian aboriginals, who are considered physically primitive, should be culturally most retarded.

This does not necessarily mean that the white's present position of dominance is assured, nor that it is to be interpreted as meaning all-round superiority of the white race. Boas lists such factors as superiority of inventions, extent of scientific knowledge, complexity of social institutions, efforts to promote the welfare of all members of the social body as marks of advancement. It may well be that the last named is of paramount importance. Humanitarianism is by no means a feature of civilized behavior today, and scientific inventions seem at present to be applied largely in the business of killing people at an unprecedented rate. Thus the supremacy of the whites may be temporary. Internecine warfare, race suicide, multiplication of neuropathic strains, devotion to the gadgets of ease or luxury may be definite threats to the present advanced status of the white race.

With regard to the Australians, there seems to be a suspicious unanimity of opinion regarding their alleged situation at the very nadir of human development. They are very generally termed "the lowest of mankind." Nadel (26), for example, pronounces the Central Australians "culturally the most primitive and backward race on earth." This suggests that a really complex matter—the determination of comparative backwardness—is being disposed of in a too facile manner.

Material culture, for example, is not a sufficient criterion of racial status unless environmental handicaps are fully allowed for. People stranded on a geologically recent volcanic isle

will find no metals available for tool making, whereas obsidian and other volcanic rocks are well suited for the making of implements. Therefore such people will remain in the Stone Age. What is made with the tools is more important than the type of tools used. Similarly, the absence of permanent houses is not a proper criterion of culture. A people condemned by sparsity of food to constant foraging would be foolish to try and set up permanent habitations. In the Kalahari, for example, the free-ranging, hunting Bushmen are much better off than the sedentary Bakalaghadis, who are anchored to one spot through their habits of primitive agriculture.

Following up this discussion of who and what are primitive, we may now turn to a consideration of the various facets of mentality or intelligence which primitive people display. Mentality is by derivation the wider term, intelligence being more concerned with the cognitive aspects of mental life, but for the purposes of this article the two terms will be considered synonymous.

For a comprehensive definition of intelligence we may turn to Stoddard (37), who finds it to be the ability to undertake activities characterized by difficulty, complexity, abstractness, economy in speed and effort, adaptiveness to a goal, social values, and emergence of originals. It also includes the maintenance of such activities under conditions that demand concentration of energy and resistance to emotional forces.

Thorndike (38) seems to base his definition of intelligence on what intelligent people do; so he lists abstract, mechanical and social intelligence, energy, persistence, self-control, leadership, various professional skills, and individual adjustment to reality "without evasions or regressions to childish and perverse solutions."

It is obvious that native Australians' mentality falls short most of all in abstract intelligence. With no words in their languages beyond three or four, arithmetical ability is sorely limited. Though they possess general classificatory terms such as "fish" or "tree," these are not plentiful. Love,³ who has studied the language of the Worora tribe, states, for example, that the aboriginal translation of "I am deeply concerned" would be "My belly is boiling." Ob-

³ From a private communication to the writer.

viously, under such conditions abstract expression is very restricted.

Originality is also not likely to be very marked, the cultural trend being against its appearance. Departures from the conventional way of thinking and acting are socially disapproved. Especially is this the case with primitive peoples, where, as in Australia, government by the elders is the rule.⁴

As regards mechanical intelligence, there is little displayed except in the operation of pressure-flaking quartzite spear points and in the fashioning of wooden spears, boomerangs and clubs. Only in social intelligence does the Australian show to advantage. Before describing his development in this respect, however, a more suitable and comprehensive definition of mentality might be sought, one particularly that will apply to both animal and human capacity, to the primitive as well as civilized men. The application of all the specific requirements under both Stoddard's and Thorndike's definitions would place the Australian in the category of the hopelessly backward and would make his survival almost incomprehensible.

The writer (20, 32) has proposed a definition with a biological basis and has suggested that intelligence is the capacity to respond to an increasing range and complexity of relevant stimuli. A relevant stimulus is further defined as one to which it is biologically advantageous for the organism to respond. Animals may have exactly the same environment, but the more intelligent will find many more relevant stimuli to which they can respond than the less intelligent. On the other hand, certain environments limit the responses of their inhabitants.

For example, leisure to exploit the environmental opportunities,⁵ to extend the range of relevancy is a necessity for progress, but this is denied the Australian. Travel is so restricted by geographical and other conditions that the native is anchored to a limited area. Waterways, except in one corner of the continent, are so few that canoes or boats cannot be used as a

means of travel and transportation. There are relatively few offshore islands so that only in the tropical regions are dugouts or catamarans in use.

Then, too, there is no animal except the kangaroo large enough to serve as a beast of burden, and the kangaroo's saltatory gait makes it useless for such a purpose. Furthermore, as most of the animals are marsupials, milk glands are little developed, and so the native is handicapped in comparison with racial groups that have been able to domesticate the mare, the camel, the goat, sheep, or other milch animals. Finally, as a crowning disability, Australia does not produce barley, millet, wheat, oats, Indian corn, or other grain so that only tiny grass and nardoo seeds are available for grinding into flour. Only those who have watched the harvesting, winnowing and milling of these seeds by native women can appreciate the labor involved to produce a small cake. Add to this ordinary sparsity the effects of droughts prolonged as much as six years and you will realize how repressive the Australian environment is, and how deficient it is in so many things that mankind elsewhere has found relevant to both survival and progress.

In one respect the cultural set has militated against advancement. The Australian has a deep-rooted distrust and dislike of strangers. Thus though the Malays have visited the northwest coast of the continent for hundreds of years and though a narrow strait is all that separates Australia from the Papuans to the north, there have been singularly few cultural importations, the pattern of social life and material culture presenting similar features throughout the continent. Except along a coastal fringe there seems to be little evidence of any substantial mixture of blood. Thus the attitude of the Australians has accentuated their isolation.

One fact has been repeatedly cited as proof of the natives' illogicality and crass stupidity. This is their denial, even in the face of such evidence as the appearance of half-castes, of physiological paternity. They are said to explain the light color of the half-white child by saying that perhaps the woman had been eating too much white man's flour. Even anthropologists have been impressed by this persistent denial of the results of ordinary observation, notwithstanding the fact that all the implications of

⁴ There are no chiefs in Australian tribes, but leadership is vested in a headman, who does not exercise authority arbitrarily but only in consultation with the tribal council, usually composed of the older men.

⁵ In civilized society the genius in abstract thinking may be set free from food seeking to pursue his abstractions. In Australian society an Einstein while occupied with his theory of relativity would starve.

fatherhood are present in aboriginal tribal customs. Ceremonial or cult totems, through which the individual shares in the psychic life, the traditions, secret ceremonies, etc., of the tribe, are matters of patrilineal descent. Filial relationships also are freely recognized, any man will point out his "properly father" as distinguished from those to whom he applies the classificatory term which means "father."

The reason for this strenuous negation of observed facts was first suggested by Lang (23) and adopted by the writer (31). The former pointed out that southeastern tribes not only recognized paternity but ascribed to the male parent the most essential part in reproduction. The mother was merely the receptacle for the unborn child. Discussing Arunta beliefs, as set forth by Spencer and Gillen (21), Lang asks whether their nescience of obvious facts is not the result of the aborigines' faith in reincarnation. They believe that the spirits of the unborn are collected at various centers, such as prominent rocks, caves and waterholes, where they await the opportunity to enter the bodies of women. Among the Arunta, which particular center or *Knanimja* is the place of origin, is revealed to the fathers in dreams. This belief is the nucleus of aboriginal religion. The native believes in both bodily and spiritual conception, and when questioned on this point is more concerned with his statement of what he believes to be the more important fact. The white investigator is therefore misled, in the same way as an enquirer, ignorant of Christian belief, would be puzzled by many civilized individuals' insistence that God was their father.

Other observers, such as Basedow and Roheim, agree that the old men at least know the facts of generation, though the tribal elders are anxious that the young men remain orthodox in their beliefs. As a matter of fact, the native knows very well the essential part played by intercourse in relation to generation. Not only does he know in most cases the paternity of half-caste children, but he is aware of cross-breeding in animals. Dingo pups with some greyhound blood are highly prized for their combination of the speed of the white man's dog with the hunting skill of the dingo. The aboriginal's doctrine of pre-existence does not, as Elkin (10) suggests, prevent him from recognizing the facts, but merely from admitting them.

Recently Warner (39) has brought forward convincing evidence on this point. During his first eight or nine months' stay with the Murngin, a group of tribes in North East Arnhem Land, he could "find no indication whatsoever of knowledge of physiological conception." Yet reviewing the total situation and the many practical implications of paternity, he was convinced that the natives must understand the mechanics of conception. On a second visit to the area when he continued his former discussions of the topic, he asked a question regarding the function of semen. He was met with expressions of contempt for his foolishness in making such a naïve enquiry when everyone knew that that was what made babies. Warner also suggests that this fact was not considered important in comparison with the natives' philosophic concepts. Thus faulty observation and interpretation of native statements is the basis of Frazer's oft-quoted animadversion (14) on the Australians: "A people so ignorant of the most elementary of natural processes may well rank at the very bottom of the savage scale."

There is another view current among many anthropologists which, if uncritically accepted, would also indicate that the mentality of the aborigines is of a low order. As is well known, the system of Australian kinship terms, embracing every member of a tribal horde, is most complex, for it not only fixes the relationship but prescribes the social observances proper to each. The writer was one of a group of whites to whom were assigned exogamous subsections and totems by our Arunta hosts. Immediately this determined my relationship to every one in the local group. There are eight of these subsections, and as a Pungata man I was the potential husband of all the Mbichana women, brother to the men and women of my own subsection, son-in-law to all the Knuria men and women, father to the Ngala, and stood in various degrees of relationship to all the rest. I could have no direct communication with any of my prospective mothers-in-law, should not speak to my younger sisters, and even in camp was supposed to sit facing a certain direction when talking to various men of the tribe. Needless to say, I found the rules too complex, disregarded them all, and was put down in aboriginal opinion as a most untutored and irresponsible person, whose ignorance was so

appalling that it was best treated as a joke. Only when I had food or cigarettes to distribute were the rights of my new relatives the subject of rather gentle reminders.

"The value of these subsections and in lesser degree of the sections and moieties," according to Elkin (11), "is to summarize kinship terms with their associated privileges, avoidances and duties, and to simplify the adjustment of these matters between tribes which differ in language and in details of their social organization." Elsewhere, Elkin states that the kinship system codifies mutual behavior, and "is the anatomy and physiology of aboriginal society."⁶ This simile would be entirely satisfactory and very illuminating if it were modified somewhat. Kinship is the anatomy, and social behavior the physiology of native society. In other words, the relationship system represents the structure, social observances the function.

It would, of course, be unwise to place undue emphasis on structure. We find Elkin stating that "the purpose of the subsection system and also of the section system seems to be concerned more with the descent of groups through the mother than with the control of marriage."⁷ If this were so, then it would seem that the establishment of this elaborate kinship system was not to codify behavior, but as an end in itself. Certainly the regulation of sex is far more important than the application of a kinship system that extends far beyond close biological ties. Everywhere distribution of food and regulation of sex are essential to the preservation of society, and under Australian conditions of sparsity both are of primary importance. If the kinship system were an end in itself, then its devising would merely make life more complicated and troublesome, which would constitute no evidence of high social intelligence but its reverse. Field workers, such as Kaberry (21), have emphasized the interest of native women in matters of sex, while Warner and others have noted that sex and food are the chief preoccupations of men. The proper regulation of such matters is vital. It is only in small communities, such as the Australian, that everybody can be brought within the compass of kinship. Hence, the aborigines seized on the kinship system as the basis of social regulation, which was a very intelligent procedure.

As Elkin rightly observes, the system was made for man, and not man for the system. This is proved by the way in which the regulations are modified to avoid individual hardship, as, for example, where no "straight" marriage is possible for a man. It is also adjusted to fit special circumstances such as the entertainment of a stranger in the camp. A reasonable statement of the situation would be that the Australians found it necessary to establish a set of social regulations and observances applying to sex, tribal authority, rituals of intercourse, inheritance of ceremonies, food distribution, etc., and found the kinship terms a most convenient system whereby these things could be done. Kinship thus superseded kingship as found in other societies, custom and ritual taking the place of personal authority.

To put the preservation of the ties of human relationship above the regulation of behavior would be to place the psychological cart before the horse. As a matter of fact, the aborigines in some respects care less about the obligations of kinship as such than we do. For example, infanticide is quite common and is not specially condemned, if the care of the unwanted infant interferes with the welfare of an older child, as it may well do under nomadic conditions. On the other hand, observances related to sex are very strictly upheld. Mother-in-law avoidance, which comes about as a consequence of a sex relationship, is the strongest social taboo, and adultery is a very serious offense.

Generally speaking, the Australians present an excellently integrated social structure which is strengthened at many points by expedients that make for social cohesion. The subsections, or sections, not only regulate marriage, but in so doing they diminish the dangers of competition for wives among the old men, the rulers of the tribe. Their authority and prestige are strengthened by the initiation rights and by the rules for food distribution. If the tribal elders were divided by serious competition and strife, the whole social system would be disrupted. Because of primitive man's tendency to ritualize all behavior, the sections and subsections have come to regulate much more than marriage, but that in the writer's opinion is their primary purpose.

Whereas Elkin regards the subsection system as a means of summarizing kinship terms, Warner speaks of it as "an extension of the kinship

⁶ *Loc. cit.*, p. 46.

⁷ *The Australian Aborigines*, p. 96.

system," and points out that each section among the Murngin has two subsections into which an individual may marry. Thus, while there are eight named subsections, this tribe is of the four-section type in regard to marriage. This does not, however, prove that marriage is not regulated by the system of sections in the Murngin and by subsections in other eight division tribes.

Confusion of thought would be avoided if the whole structure of named divisions of tribes were regarded as a method, founded on kinship terms, of codifying sex relations, and one which is in some tribes in process of development. Among the Aluridja (Luritja), for example, there were no named divisions, marriage being regulated solely on the basis of kinship terms. The writer, however, found evidence that Luritja in contact with the Arunta were beginning to adopt the latter's eight subsection system. Other tribes, especially in the South-east, were divided into two halves or moieties. Moiety names, such as Eaglehawk and Crow, would, of course, have little value in summarizing kinship terms. In still other tribes, notably on the Northwest coast, the Kariera type of four named sections regulated marriage. In Central Australia and the southern Kimberley area, the eight subsection system prevailed. Tribes such as the Murngin are apparently in a transition stage, their subsection system simplifying or summarizing the kinship terms, but as yet not controlling marriage, which remains one of the functions of the sections.

Thus it would seem plausible to regard the Australian system as a developing process in which subsections originally evolved from sections, sections from moieties, and moieties out of ungrouped kinship terms. In short, they are kinship groupings applied *principally* for the regulation of sex relations. Regarded in this way, the system is proof of Australian social intelligence since it exemplifies progressive adaptability, and the ability to respond to a complex situation. On the other hand, adherence to a kinship system, involving every member of a tribe of, say, two hundred persons, as an end in itself would be tantamount to saddling themselves with a cumbersome method of making social behavior needlessly complicated. This in itself would be no evidence of mentality, but merely of the tendency of primitive man to ritualize behavior. If this behavior

could be codified, then that would mean a long step in advance towards a more ordered existence, making for tribal cohesion. Since this has been done, it is, in the writer's opinion, proof of aboriginal planning, and therefore of intelligence.

Mention should be made of another animadversion on aboriginal mentality. This is to the effect that the native is extremely unforeseeing and improvident since he makes no attempt to store surplus food. This improvidence is more apparent than real. Blow flies are so prevalent that meat cannot be subjected to any sun-drying process, while plant supplies are so scanty that it pays the natives to move off to new hunting or collecting grounds rather than to set up granaries for a pitiful surplus, if present. In extended droughts permanent water rather than food supplies determines the nomadic range.

On the other hand, the natives take the best means they know to conserve food supplies, means that in their opinion are much more effective than storage. When there is any time to spare, the men of the horde, under the careful direction of the old men, devote themselves to the carrying out of "increase ceremonies," whose object is to ensure not only the continuance of animals and plants used for food, but the whole balance of Nature. The Australian aboriginal lives by faith much more nearly than the modern Christian. This devotion to his religious beliefs cannot be advanced as proof of primitive man's inferior mentality, except perhaps under the heading of what Thorndike calls persistence "in perverse solutions." We also occasionally pray for rain.

Brief reference should also be made to the well-known theories of Levy Bruhl and Durkheim, which assume fundamental differences between primitive thinking and that of civilized man. This thinking, they believed, is pre-logical in that primitive people are swayed, not by individual conclusions, but by collective representations, products of the group mind. Further, the primitive mind is supposed to be unable to separate the mystical from the real, so that logical evidence has no appeal. It is more reasonable to conclude that primitive man's thinking is pre-scientific rather than pre-logical, much as is a great deal of the thinking of people in our own society. Boas rightly emphasizes the influence on thinking of the body of traditional knowledge, in the light of which a given experi-

ence is interpreted. Reasoning, he says, "becomes more and more logical, not because each individual carries out his thought in a more logical manner, but because the traditional material which is handed down to each individual has been thought out and worked out more thoroughly and more carefully."⁸ In short, primitive man accepts more that is unproved, needs less support for his conclusions, and possibly becomes more emotionally involved as regards his beliefs. He is illogical and pre-scientific, rather than pre-logical or completely unscientific.

So far we have dealt mainly with the primitive Australian's reactions to his natural environment and the statements that have been made which seem to reflect too harshly on the narrowness of the range of relevant stimuli to which he responds in that environment. We may accept the fact that he displays abilities such as persistence, energy, self-control, social intelligence, leadership, and special skills involved in his almost miraculous feats of tracking animals and men. Economy of effort, adaptiveness, and concentration are also called for if he is to cope with that environment, but these all have limited application.

As the result of white settlement of a considerable part of the continent, the aboriginal has been confronted in the last hundred years or so with opportunities to increase the range and complexity of his responses to relevant stimuli. If we are to get a measure of his progressive adaptability we must enquire as to how he has availed himself of his changed environment. For those tribes in contact with whites the conditions of existence have been essentially changed. The transition from the stone to the machine age has been most abrupt, perhaps so abrupt that native life will be extinguished in the process.

This process of extinction has unfortunately taken place over large areas of the continent, especially in the fertile southeast. Elsewhere, it is going on rapidly. The building of the East-West railway line, for example, has resulted in complete or partial tribal disintegration throughout a strip of country several hundred miles wide beside the tracks. Handouts of food and cast off clothing have induced the natives to forgo their traditional localities, notably near Ooldea, where there are supplies of permanent

water. The railway line to Alice Springs, 1,000 miles to the north from Adelaide, and the construction of the military highway to Port Darwin have changed the face of the country and the lives of the natives. Trains, airplanes, automobiles have now become a common part of the outback scene. Can they become relevant in aboriginal environment?

The fact that native survival is dependent not only on food but on their participation in the psychic life of the tribe has been underscored by Elkin (12). He states that "the aborigines had reached a stage of satisfactory adaptation to their environment—economic, social, and religious. But the coming of the white man meant a radical change in the environment—radical because spiritual, though it also meant, and means for most natives, a new economic orientation, and soon, though not necessarily, a change in the social ordering of life." Through the decay of tribal life, the non-transmission of myths and ceremonies, the breakdown of social sanctions, the native becomes attracted to the white settlements where he loses his virtues and becomes a degraded hanger-on to the skirts of civilization.

Elkin believes that education for the new life is the only solution. He would include the teaching of reading, writing and arithmetic and simple industrial techniques to fit the aboriginal to take his place in the new order. The question then arises as to the native's mental ability to assimilate such instruction.

A very sanguine estimate of this ability has been founded on a very dubious statement that crops up from time to time in the literature. In 1881, Dawson (8) reported that an aboriginal school at Ramahyuck in Victoria had achieved a most remarkable record. He stated that the percentage of marks gained in examinations by government inspectors was 100, "a result unparalleled by any other school in the colony." Mathew (25) in 1899 repeated this statement and it was again quoted by Lefroy (24), and more recently by Ashley-Montagu (2).

The facts throw a different light on this report. Schools in those days were compared on the basis of promotions attained by pupils, not examination marks, and a diligent search of the records shows no higher percentage of promotions for Ramahyuck school than 94. Furthermore, each inspector set his own examination and no doubt tempered its difficulty to

⁸ *Loc. cit.*, p. 223.

aboriginal mentality. No mention either is made of the age of the children promoted. On the face of it, the record, being so much at variance with all subsequent experience, is incomprehensible except on the grounds of acceptance of extremely low standards of achievement for the aboriginal pupils. Mathew, indeed, qualifies his praise by saying: "While among Europeans the range of mental development seems almost unbounded, with the blacks its limit is soon attained. An inherent aversion to application is generally an impassable barrier to the progress of an aboriginal's education."

We find, too, a very pessimistic note appearing in Elkin's recent summary (12) of the results of those educational efforts on behalf of the aborigines which he so earnestly recommends. After analyzing the opinions of forty teachers of aboriginal children throughout the country, he says: "So far, they (the aborigines) have not shown themselves capable of adapting themselves to the new, nor have our attempts to help them been successful." He raises the inevitable question as to whether their former adaptation had not become "biological," and so specialized that the outlook for educational and social adjustment for full-blooded natives might not be hopeless. As regards education, the gist of the matter is the ability of the native to include the basic symbols of abstract thought within the range of his relevant stimuli.

It must be admitted that schooling as offered to the native is not of a very high order. Elkin mentions lack of trained teachers, obsolete methods, late age of school entrance, pidgin English, and retarding influence of home or camp life as special handicaps. Keeping these things in mind and giving most weight to the evidence of trained teachers, he summarizes their opinions on native abilities as follows:⁹

- (1) Full blood children seldom pass beyond the third standard, occasionally reach the fourth, and very rarely go higher.
- (2) More years are spent reaching these standards than are taken by white children attending the same schools.
- (3) Except in rote learnings, writing and manual subjects, aboriginal children are markedly inferior. "Parrot learning is the rule." "Not one of my informants," says Elkin, "even suggests that the aboriginal

pupils are the equal of white children in school, even before puberty, and this they maintain is true of half-castes.

- (4) Departmental intelligence tests applied to sixty children of mixed blood revealed three years' retardation, whereas white children attending the same schools proved normal.
- (5) Full blood and half-caste children, though equal to white children in mechanical work, soon reach their limit in educational development. There is practical unanimity of opinion that progress does not continue after puberty.¹⁰

Though Professor Elkin doubts the ability of the psychologist "to put his tests across," the picture which they present of primitive mentality is in one direction at least more promising. Tests of practical intelligence involving planning capacity, such as the Porteus Maze, present by no means unfavorable results.

These tests are certainly not, except to a very limited degree, "matters of culture and tradition and not just of individual mental capacity" as some cultural anthropologists believe. It would be difficult to prove that running a course through a graduated series of printed mazes is part of a white child's tradition and culture. With the aboriginal's almost photographic memory for terrain, and his constant necessity to orientate himself correctly in the bush, the maze test presents a problem to which his mental set is by no means averse. This is proved by the concern and anxiety to succeed which he exhibits in the test. This is testified to by investigators such as Fry and Pulleine (15), who worked with Australian natives. Kilton Stewart, who applied the Maze test to Ainu, Philippine Negritos, Formosans, Senoi of Malaya, and Bajou of Borneo, and the writer (33), who examined African Bushmen and noted their extraordinary interest in the test. Fry and Pulleine remark, "While watching a

¹⁰ No mention has been made of aboriginal art. Compared with Bushman cave paintings this is by no means highly developed. Nevertheless, there is probably much latent ability. Albert Namatiira, a full-blooded Arunta, after some instruction by Rex Batterbee, an Australian artist, for whom he acted as camel boy, has shown extraordinary talent in water colors, his paintings having been exhibited and reproduced in a recent book entitled *The Art of Albert Namatiira*, by C. P. Mountford, Melbourne, 1944.

⁹ *Loc. cit.*, pp. 488 ff.

native at work on these problems one can almost feel the intensity of the mental strain involved." Dubois (9), working with the people of Alor, found that as soon as the tests began to be difficult, her subjects perspired freely and their body odor increased. To any writer familiar with the casual and perfunctory approach of primitive subjects to a test in which they are not really interested, this evidence of anxiety to succeed disposes fully of the suggestion that the maze test has not been successfully "put across."

The results of these maze applications offers no support to the view that the Australians represent the lowest of mankind. The score of one group, mainly of Arunta, who had been in contact with the Lutheran mission in Hermannsburg, averaged 12.08 years (0-2.087). Several Luritja, who had come in from the desert and up to a few days previously had never seen a white man, were included, and one of these made a perfect score.

Piddington (30) also examined 24 adult males at La Grange in Western Australia and found their average to be 10.52 years, which was almost exactly the score obtained by the writer with 65 adult males in the Kimberley district about 300 miles to the east. Fry and Pulleine's group of Iliaura natives averaged 10.7 years, which may be accepted as the maze performance of aborigines who have had no contact with missions.

This score may be compared with that of other primitive groups elsewhere. "Raw" natives belonging to three African tribes, Mchopi, Shangaans and Amaxosa, were examined by the writer (33). The last named tribe, who are Zulus and familiar with a labyrinth game played by means of a design drawn in the dust, scored 10.78 years (0-2.76), while Shangaans averaged only 9.3 years (0-2.66), and the Mchopi 8.34 (0-2.45). Thus though these Bantu tribes are culturally placed much higher than the Australians, they did not, with the exception of the Amaxosa, score nearly as well as the aborigines.

Natives of three other tribes, Bathonga, Wakaranga and Vandau, all of whom were being educated at mission schools, may be compared with the Central Australians at Hermannsburg mission. The average performance was about a half year in test age below the aborigines. Here again the advantage lay with

the supposed cultural inferiors. Bushmen of the Kalahari could only average 7.56 years (0-2.17) in spite of their intense interest in the test.

Kilton Stewart, under the writer's direction, applied the tests to various primitive peoples in East Asia; Bajous or sea gypsies of Borneo scored 10.61 years and Senoi or Sakai of the mountains of Malaya 10.43 years, but Negritos of Luzon averaged only 8.88 years, while the coastal Sakai Jeram, a very backward tribe on Malaya, scored 8.02 years, not much above the Bushmen.

Anthropologists have questioned the significance of maze test results. At least 85 per cent of defectives, irrespective of race, make extremely poor scores in this test so that it has widespread use as a diagnostic measure. It can be applied independently of language, and adults who have never before handled pencil and paper seem to be able to master the technique of drawing between the lines notwithstanding, as one investigator remarked, their astonishment at seeing the "trail" or spoor follow the pencil. Recently new light has been thrown on the question of maze score significance, through the effects of the brain operation of prefrontal lobotomy.¹¹ These show that when the organization of the brain in the frontal lobes has been impaired by severing the sub-cortical connections with the thalamus, there is a marked decline in maze test performance. In the feeble-minded this organization has never been fully developed.

Another study by O'Shea and others (28) indicates that artificially induced Vitamin B deficiency will also be reflected in poor maze scores and that improvement in test response proceeds proportionately as the deficiency is made up by feeding with B complex.

The observed practical intelligence and social planning of the Australians correlates well with their Maze test performance. Unfortunately, their poor educable capacity is indicated by extremely low scores in other tests (31). In an auditory rote memory test for digits, the memory span of adult males was found to be less than four digits, a white four year level. All the subjects were familiar with the names of the numbers up to ten. Mission Bathonga, on the other hand, scored an average of 5.34 digits, a performance fully 4 years in test age above the Australians. Clinical observations show that

¹¹ See article under this heading.

individuals with marked deficiency in rote memory have great difficulties in mastering the rudiments of either reading, spelling or arithmetic, commonly all three. That has been the experience at the Psychological Clinic of the University of Hawaii, where several thousands of educationally retarded Filipino, Japanese, Chinese, and part-Hawaiian children have been tested.

Visual memory was also determined by a xylophone arrangement of the Knox Cube Test, in which four bars were struck in series to be reproduced by the subjects. No doubt because of this visual presentation the Australians scored much better in this test, averaging 8.33 years in test age. But they were excelled by all the Bantu tribes except the Bathonga, the Vandau being a full year superior to the Arunta.

In Goddard Form Board times, the Australians and Bushmen had the slowest times, the South African natives excelling the other primitive groups. In a test of matching photographs of footprints, the performance of all the native groups was more nearly equalized.

In regard to other examinations of primitive mentality, if we reject from the list those of the Binet type which depend on language to such a degree as to be obviously unsuited for their purpose, we are left with singularly few of any importance, and even those employ a very narrow range of tests. In 1904, Woodworth (49) applied a Seguin Form Board test to Igorots, Pygmies and Negritos exhibited at the St. Louis Exposition, thus establishing a pioneer record. His conclusion reads: "If the results could be taken at their face value, they would indicate differences of intelligence between races, giving such groups as the Pygmy and Negrito a low station as compared with most of mankind." This position has been occupied by these racial groups in subsequent investigations. Tests scored on speed are usually not dealt with successfully by primitive peoples, but the error score of the Pygmies and Negritos was similarly inferior.

Garth (16) reported work with various American Indian groups, but unfortunately used a group test, the National Intelligence Test, which is obviously unsuitable. The Pintner Non-Language scale was applied by Owen Smith, a student of Garth's, to full-blood Indians in schools in the Southwest of the United States, and their average I.Q. was only 71.6. However, this scale also, though not dependent

on language, was hardly suited to the cultural background of Indians. The study was reported in 1931. Blackwood (5) reports another study with Indians but used an unstandardized scale, the Squires International Test.

In 1930, Nixen, Machover, and Kinder (27) gave performance tests to 50 native children of the Soussou tribe in French Guinea, Africa. They tried out 12 performance tests, six of them taken from the Army Performance Scale which was arranged for adults and was therefore unsuited to younger children. Strangely enough, one of the tests applied was the fitting together of the parts of a picture of a ship, though the natives had never seen even a canoe, let alone a ship. These authors' conclusion that the inferiority of their subjects in test scores is "unequivocal" must, as they point out, be cautiously interpreted. They note that their cases seemed to work harder at the Maze test than at any other.

One of the most careful studies of primitive mentality was that conducted by Vicary (41) in North Bengal, his subjects being immigrant Santals and individuals of other aboriginal tribes attending a mission boarding school. These people are considered to be Dravidian or pre-Dravidian in origin and "represent tribes which have retained their primitive tribal organization almost unimpaired, though they have wandered far from their homes in the low hills of the Chota Nagpur plateau."

Out of twelve commonly used performance tests, Vicary found three to be reasonably valid and applicable. There were the Porteus Maze, the Knox Cube Imitation, and the Goddard Form Board. The Maze test correlated highest with all the other simple tests and highest with the sum of these, showed the most regular growth development, proved most suitable for retesting, and was the heaviest loaded with "g" in factorial analysis. The weighting finally allotted to each of the three tests when combined in a scale was Maze 5, Goddard Form Board 2, Cube Imitation 1.

The Maze test score of 59 Indian male aboriginal subjects over 14 years was 9.52 years as compared with 104 Australian adult aborigines' average of 16.97 years. Thus the superiority of the Australian performance in the Maze was again demonstrated. But in the other two tests the situation was reversed. The Australian males averaged only 8.3 years on

the Cube Imitation Test, while the Indian aborigines averaged 9.08 years. The latter's advantage was even more marked in the Goddard Form Board in which the Indians scored 9.89 years as against an 8 year average for the Australians. These results agree with those reported by the writer with regard to six South African Bantu tribes. The Indian aboriginals were, however, superior to the African Bushmen in all three tests.

Fick (13) also reports results of an extensive study of South African native school children. After using a variety of performance tests, his choice narrowed down to four. Two of them, the Porteus Maze and Cube Imitation (Knox) had been, as we have seen, already applied to primitive peoples, and the others were the Worcester Form Boards and a South African test, the Match test of Malherbe. Fick first examined over 500 children in a preliminary study and then applied the four tests, combined as a scale, to 180 twelve year old children attending urban and rural schools. Fick's conclusion was: "Around the ages of 13 and 14, native children are from 4 to 5 years inferior to European children in educability as gauged by the results of intelligence tests."¹²

Anderson and Eells (1) carried out a study in Alaska, but since they used a modified Binet their results are not particularly germane to our subject. They did, however, apply the Goodenough Test and found that the derived I.Q.'s were for Eskimo children 89.6, Indians 91.6, and Aleuts 93.3. These figures may be compared with an I.Q. of 77.4 for Central Australian full blood children, 89 for three-quarter blood aborigines.

It will be noted that in this survey of studies of primitive mentality scarcely any reference has been made to the results of group tests. Clinical psychologists for various reasons regard these as much less valid than individual tests and almost wholly unreliable for the purposes of mental diagnosis. As regards their application to primitive peoples, they are entirely impossible. Even if non-verbal in character their application depends on verbal instructions. Frequently, as was the case with Mann's study of children in Fiji, they are applied and scored by teachers, rather than by psychologists. For the purposes of this article they are considered to be of very questionable significance.

This leaves a very restricted list of investigators using individual performance tests. Out of 98 references cited by Mann in a recent survey (*Psychological Bulletin*, June 1940), only 13 had first-hand experience with this kind of testing of really primitive subjects. This fact diminishes seriously the significance of Klineberg's recent statement to the effect that the writer is one of the very few investigators who still believe that race differences exist. There are, in any case, very few investigators of primitive mentality, and their results show a rather remarkable agreement in proving that primitive peoples differ not only from whites but also among themselves. In regard to their status in intelligence, the situation may be summed up by saying that though they are excellently adapted for survival in their original simplified environment, they are much less equipped to deal with the rapidly changing world that surrounds and threatens to engulf them.

PROJECTIVE TECHNIQUES. — Projective techniques refer to a group of psychological methods which are characterized by more or less free responses to more or less unstructured stimuli. For instance, a person may be shown an ink blot and asked what it resembles or what he sees in it. Psychologists have been interested in free responses to stimuli for years, but formerly this interest was concentrated on what the response might indicate concerning the ability of a person. More recently, however, it has been discovered that behavior is an expression of inner drives, impulses, feelings, fantasies, and conflicts, and by permitting the free choice of the response to be made to a stimulus one learns the direction and nature of the individual drives, preoccupations, feelings, and conflicts. Accordingly projective techniques cannot be defined merely in terms of the free responses to stimuli, but they must also be defined in terms of the interpretation of the meaning of these responses for the light that they may shed on personality. Projective techniques have piqued the curiosity of psychologists because they promise to serve as a means of investigation of some of the dynamic factors in personality.

Projective techniques may be contrasted with psychometric methods. The latter ask questions for which there is only one correct answer and the individual is challenged to produce that answer. Psychometric methods have also been employed in the study of the answers to questions where there is no one correct answer, but where the answer is an expression of the individual's interest, attitude, or adjustment. But in these questionnaires the range of answers is definitely limited. In a questionnaire one has to say whether he does or does not have frequent headaches, whether he does or does not like to sing, does or does not believe in group medicine as a wise social policy. Projective tech-

niques differ from these questionnaires by permitting greater scope in the response. A child may be asked to draw a man and may include (or not according to his wishes) two arms or two legs. And since specific questions are not asked, but a person is challenged to tell a story, draw a picture, mold clay, or interpret an ink blot, he is not aware that the choice, nature, and quality of his product or response will be interpreted to indicate his personality characteristics.

The term projective technique was first used by L. K. Frank (5) in a paper published in 1939. It represents the conflux of two widely different streams of psychological interest and method—psychometrics and psychoanalysis. For years psychometricians had been exploring the nature of the free response. As early as 1879 Galton (8) experimented with free association to words as stimuli. Cattell and Bryant (4) were also experimenting with free association in 1889. Binet with his collaborator Henri (1) studied responses to inkblots in 1895 and also tried out sentence completion experiments in the same year. G. Stanley Hall's eclectic interest in child study led him to explore a number of children's interests and one of his students—Brittain—in 1907, in a study of daydreams, explored the kinds of stories that children write to the stimulus of pictures, anticipating by many years Murray's (19) use of the same procedure as a projective technique. However, each of these investigators was interested only in the responses, which they classified and tabulated and used vaguely to estimate the mental development of a person, and they did not use them as a means of understanding the nature of a person's inner life.

Freud was the first to discover that the products of a person's free associations were related to his inner drives and conflicts. In his study of dreams Freud (7) asked his patients to associate freely to the dream and its elements, and by relating elements in a string of associations he was able to discern significant facts concerning a person's inner life and his unconscious mental processes. This method of free association became the primary tool of the psychoanalytic method by means of which unconscious processes were revealed. In the free association of the psychoanalytic method no stimuli are used—the patient is asked to let his

mind wander as it will. In using projective techniques the psychologist is abandoning perfectly free association for the free response to selected stimuli. This first step toward standardization of the free association method makes possible controlled observation, and the comparison of free responses to a standard stimulus. By controlling the situation in this way the psychologist meets part way one of the demands of scientific method—the reproducibility of the experiment—which free association could never fulfill. Projective techniques also help to systematize the response in a way not possible in the interview and systematize both the situation and response beyond that possible in free observation.

Free association to words as stimuli were first used as a projective technique by Jung early in the century (1904), although his treatise on the subject was not published in English until 1919 (13). The use of ink blots as a projective technique was experimented with by Rorschach for a decade or more before he published *Psychodiagnostik* in 1921 (23). Neither the free association method as a projective technique (it was used following Kent and Rosanoff (14), by comparing common and unusual associations) nor the Rorschach method claimed much attention or usage among psychologists until recent years. The Thematic Apperception Test (telling stories to pictures as stimuli) as developed by Morgan and Murray (19) in 1935, and Murray's book *Explorations in Personality* (20) in 1938 gave the impetus to the modern development of projective techniques.

The application of the psychoanalytic method to children has contributed greatly to the development of the projective method and projective techniques. Freud himself was the first to apply his psychoanalytic method to children in his study of a five-year-old boy with a phobia (6). This method was also studied by Von Hug Hellmuth (12), but it was Melanie Klein (15) who showed how a child's play can be interpreted to reveal important characteristics of a child's inner drives, feelings, and conflicts. Out of her work has developed the interpretation of children's play and of the products of children's imagination in painting, drawing, clay modeling, the building of models and the manipulation of materials—all to be classed as projective techniques.

MEDIA

Projective techniques have used a variety of media. It is appropriate to range these from the completely unstructured stimulus such as a lump of modeling clay to those which are highly structured such as a doll or a photograph. The crayon and the blackboard or pencil and paper is the limit of the unstructured situation inasmuch as the stimuli to be responded to have no structure whatever except the shape and size and texture of the board or paper and the crayon. Since projective techniques depend on the principle of free association or free expression, it is important that the medium used gives free scope to action and provides the widest possible latitude in choice of response or form of expression. Painting and drawing are excellent for this purpose. In securing a child's drawing for use as a projective interpretation one would give the child freedom to paint or draw whatever he wishes to. The figures of men drawn in the Goodenough Drawing Intelligence Test (9) lend themselves to projective interpretation, but its value as a projective technique is lessened by virtue of the fact that the child is given a subject to draw which to that extent circumscribes his drawing.

In like manner it has been pointed out that in using pictures for interpretation they should have a minimum of detail, leaving as much as possible of the background and definitive qualities of the people in the pictures to the imagination (27).

RESPONSES

Frank (5) has made a classification of projective techniques into four types according to response, to which a fifth is here added—the *constitutive, constructive, interpretive, cathartic, and expressive*. Those techniques in which a person is given some unstructured material and is asked to mold it into some form which has meaning for him, or in which he takes relatively unstructured material and tells what he sees in it are the *constitutive*. For this purpose such pliable substances as clay, plasticine, cold cream, dough, or snow have been used. Drawing or painting belong in this first category. Finger painting with colored starch paints upon a wet paper surface have yielded significant results. Musical composition, story writing, and the interpretation of the relatively unstructured

and meaningless ink blots in the Rorschach method may also be placed in this *constitutive* category.

In the second group one *constructs* by organizing separate meaningless parts into meaningful wholes. Building with blocks is a crude example. Organizing little toy figures of buildings, people, animals, and landscape features into a meaningful whole as is done in the Bühler-Lowenfeld "World Test" (3, 17) represents the same kind of response on a higher level. Children's play with toy materials comes in this category also. If one wants to think of words as the building blocks of language, story and sentence completions are two types of projective techniques which belong in this second type.

A third type of response requires *interpretation*. Pictures which may be interpreted by telling what they mean, or what the characters in the pictures are doing, saying, thinking, or feeling, serve as convenient stimuli. The interpretation need not be too intellectual and may partake more of the nature of reverie or day-dreaming, as when one tells what thoughts and feelings a musical selection or an odor arouses in him. The response to the Rorschach ink blots belongs in this category too, as the individual interprets what he sees in them.

In the fourth type the person reacts to the situation with *feeling* so that the response may have some *cathartic* value. These reactions may be overt and manipulative, as when a child does violence to a doll figure whom he takes as a surrogate of some member of his family; or verbal and symbolic as he shouts vengeance during a Punch and Judy show, or as he finds outlets for his feelings in the drawing of a comic strip. The expression of feeling may be overt and manipulative—or it may be expressed more covertly in words and speech or even by gestures and posturings.

The fifth group consists of the so-called *expressive movements*; gestures, handwriting, voice and speech, and gait; and those which have been solidified into posture, expression or profile, which may express inner feelings, tensions, inhibited impulses, and the like.

INTERPRETATION

The most important feature of a projective technique is not the *type* of stimulus provided or response given to it, but the interpretation

which is made of the response. For it is believed that a person's inner drives and conflicts will reveal themselves through a number of media and different kinds of expression. Probably time, economy, and similar practical considerations are more important criteria for the selection of stimuli for projective techniques than psychological considerations. Indeed, the best projective responses are secured with the least elaborately structured or organized equipment.

There are differences of opinion as to whether a projective technique is best interpreted by treating it psychometrically or using a more qualitative and analytic type of interpretation. Since those who first experimented with projective materials were trained in psychometrics it was only natural that early users of projective materials should have attempted a quantitative and psychometric interpretation. Even Rorschach, a psychiatrist, analyzed responses to his plates in terms of the type of response, part of the plate responded to, etc., and every person interpreting a Rorschach record first analyzes the responses and tabulates them on a score sheet. Murray in developing his Thematic Apperception Test in which interpretations to pictures are made by the person taking the test, proposed to analyze and tabulate the themes found in the stories. Attempts to score projective techniques are still being attempted, so that it is not possible to give a final answer to this issue at the present time. Murray (20) proposes that the Thematic Apperception Test be first analyzed into the force or forces in the form of *motives, trends, feelings, needs, or drives*, emanating from the hero of the stories, and the force or forces emanating from the environment which he calls a *press*. He proposes to fit the classification of the needs into a list of 28 needs which he has derived from his experience in studying needs, and then he would rate the strength of each need on a scale of zero to five. Murray suggests that the relative strength and frequency of these needs and press can be interpreted quite simply and directly as things that the subject has done or wanted to do, elementary forces in his personality arising from his forgotten past that he is experiencing in the present or that he has hopes to do or feel in the future on the one hand; and as situations he has experienced actually or in fantasy or situations that he would like to

encounter in the future on the other hand. But the exact nature of such interpretations from tabulated and rated analyses of the themes in the material is very doubtful.

It is safe to say that at the present time the interpretations of most significance are those which are purely qualitative and analytic. Murray (21, p. 7) suggests that the subject can be characterized for his "superiority (power, ability), inferiority, criminality, mental abnormality, solitariness, belongingness, leadership, and quarrelsomeness." He suggests looking for themes centering around "problems of achievement, rivalry, love, deprivation, coercion and restraint, offense and punishment, conflict of desires, exploration, war" (21, p. 13). He believes projective techniques can answer such questions as "how much force (energy, determination, enduring effort, competence) does the hero manifest? What is the strength of the facilitating or beneficial forces of the environment as compared to the opposing or harmful forces? Is the hero's path of achievement difficult or easy? In the face of opposition does he strive with renewed vigor (counteraction) or does he collapse? Does the hero make things happen or do things happen to him? To what extent does he manipulate or overcome the opposing forces and to what extent is he manipulated or overcome by them? Is he coercing or coerced? Is he mostly active or passive? Under what conditions does he succeed, when others help him or when he strives alone? Under what conditions does he fail? After committing an offense or crime does the hero get properly punished? Does he feel guilt, confess, atone, or reform? Or is the misdemeanor treated as a matter of no moral significance and the hero allowed to "get away with it" without punishment or fateful consequence? How much energy does the hero direct against himself? (21, p. 12).

Projective techniques may be divided rather sharply into two classes according to whether they lend themselves primarily to *formal* interpretations or to *content* interpretations. In general, the responses to unstructured material are best suited to formal analysis, of which the Rorschach is an example. It is commonly said that the Rorschach sheds light on the *structure* of personality. By analyzing the *location* of the *stimulus* which is responded to and the *quality* of the *response*, as well as the number of re-

sponses, the speed of response, blocking of response, and commonness or originality of response such factors of personality as tendencies toward introversion-extroversion, constriction-dilation and predilection to anxiety as well as more specific psychotic trends and signs of organic neurological disturbance can be diagnosed. The content of the response is relatively unimportant, but is not wholly disregarded in the Rorschach. But the Thematic Apperception Test reveals *content* principally and while some attention may be paid to such formal factors as "structure, style, mood, degree of realism and power of the plot and language of the stories" (21, p. 18), the stories are particularly useful in revealing content. Such products as paintings and drawings, free play with toy materials and the like yield both *formal* and *content* factors.

The term projection was undoubtedly borrowed from the Freudian mechanism of projection, but it has a far weaker (and wider) connotation than the mechanism. In a projective technique there is undoubtedly a projection as the individual projects into the product of his fantasy trends which are true of his own personality and it is on this hypothesis that the whole interpretation of projective techniques is based. For instance, in the picture-story method the impulses and trends of the characters in the stories may be projections of impulses and trends of the individual telling the story. It may also be said that the individual *identifies* himself with the characters which he *projects* into his fantasy products. While he may be unable and unwilling to admit certain trends in his own personality because to do so would be too uncomfortable and dangerous (and hence those trends remain unconscious), he is able to face them openly by projecting them into some external product of his imagination—possibly a character with whom he identifies himself in a story he has told. Murray (21, p. 6, f) refers to the hero of the story—that is, the main character of the story, the one in whom the story-teller is most interested, and from whose point of view the story is told. Murray believes that the individual telling the story identifies himself most closely with the hero. But it is also probably true that there is identification at different levels and in varying degrees with each of the characters of the story. Indeed, some minor character which plays an insignificant role may be the carrier of some

important disguised wish or role of the story-teller.

One issue with regard to the use of projective techniques is whether they can be used blind or not—that is, whether they can be interpreted without knowing anything else about the subject. To the experimental psychologist this would be a *sine qua non* of the validity of the projective method. Those with a scientific and experimental background believe that if a projective technique must be used only in conjunction with other facts and information about a person, it will be colored and biased by that material and hence invalidated. But clinical psychology recognizes the complexity and patterning of personality and believes that any single aspect of personality is relatively meaningless. There is a belief among clinical psychologists that it is impossible to interpret projective material validly in isolation and they insist that it should be interpreted only in conjunction with other facts about an individual. Indeed, the more that is known about an individual, the more meaningful and significant the projective material becomes, and the more light it sheds on the person who produced it. It is never possible to say positively that this item in a literary or artistic production signifies so-and-so about the person who produced it. One must always say that it *may* be a quality of the person, and the probability that one is correct in making such a statement grows as more is known about the person. Projective material merely helps to build up the composite picture of the personality of an individual.

One reason that one can never say with assurance that projective material means this or that about the person who produced it is that one never knows the *level* of personality from which it springs. It is a fascinating and plausible hypothesis that every production of a person represents *some* dynamic trend within him. If we knew enough, every shred of the stories a person produces would tell us important things about him. If all of the trends within an individual were at the surface, and had an immediate counterpart in behavior, then there would be a one-to-one correspondence between the fantasy material and personality. But some trends are repressed and unconscious. Indeed, the individual, in order to disguise them and hide them even from himself, may adopt exactly the opposite pattern of behavior in his

own personality. A mild person may tell stories of violence and destruction, these latter representing repressed impulses that are not permitted expression in his actual behavior, but only in his fantasy production. Murray recognizes several (at least three) such levels: the first or manifest level, the second or repressed level, and the third the symbolic or infantile level. One never knows at which level projective material is pitched, and the level can only be discovered by becoming more intimately acquainted with the person. It is a suggestive hypothesis that in emotionally stable and normally adjusted individuals there is strong resistance to revealing unconscious and repressed impulses so that there is little correspondence between fantasy material and actual life personality—the well-adjusted person lives realistically in the present but his fantasies are revivals of long submerged impulses and trends; but that in emotionally disturbed individuals the conflicts put pressure on the individual to reveal and relive his unconscious trends and they become acted out in behavior so that there is a close correspondence between fantasy material and personality. But this hypothesis remains for future validation.

From the foregoing one may deduce that projective techniques in their modern use cannot be thought of as tests which tell something definite and clean cut about a person. They merely suggest hypotheses which must be substantiated by referring them to actual life history or interview material. It is doubtful if projective techniques can ever be validated by statistical methods. The same item in a projective technique may be interpreted differently on two different occasions. If a given trend in projective material—say aggressiveness—may mean for one case that the individual shows aggression in his behavior while in another it means that his aggression is deeply repressed—then obviously no application of correlation methods is going to indicate the true nature of the correspondence. One boy may find brunettes fascinating because his mother was a brunette; another boy may repress this tendency to be fond of brunettes who resemble his mother and may himself be attracted to blondes as a reaction formation. Although there appears to be little statistical relation between the choice of companion and parental type, dynamically the same factors may be operating.

Macfarlane (18) proposes the following methods of validation of projective techniques: 1) correlation of items or elements in projective material with outside criteria, 2) comparison of the projective material with the life history, 3) longitudinal or parallel studies of projective material and life history material, 4) the experimental approach, 5) success in prediction from projective material to actual behavior. But each of these methods is in a sense inappropriate. The only test of the validity of projective interpretations is the dynamic correspondence of the projective response with the personality of the individual as revealed through intensive and analytic personality studies. Rosenzweig (24) fears lest the interpreter project his own fantasies into the process of interpretation. But this is inevitable—probably the best interpretations are those in which the experimenter interprets the fantasy material of another person in the light of his own fantasies and his experience in understanding the fantasies of others. The danger comes not in projecting oneself into the interpretation, but in failing to follow through with the check from the direct study of the person through interviewing and free association. Marfarlane also speaks of the danger of overgeneralizing from projective material. This is a danger inherent in all methods of clinical investigation and can be avoided by the demand for corroborative evidence and larger samples. The blind interpretation of projective material may or may not be worthwhile—the value of projective methods comes only as the interpretation is corroborated by the pattern of the personality as revealed by other data, preferably from direct interview and analytical study.

SPECIFIC TESTS

In the years in which projective techniques have been experimented with only a few instruments as such have been developed. First of all, there is the *word association* test, credit for which as a psychological method goes to Sir Francis Galton (8) and as a projective technique to Jung (13). In the word association test a subject is presented with one word after another and is asked to write down the first word which occurs to him after the stimulus word is presented. Jung's list of 100 words is a standard list. The Kent-Rosanoff list (14) has been used more as a psychometric device than as a projective technique. The word association

test yields words of real projective but somewhat limited practical significance. The burden is left to discovering the meaning of the responses from other material more than in most other projective techniques.

The *sentence completion* test, first tried out as a projective test by Tendler (30) and also by Hildreth and Rohde (10) yields results that are a little richer in content and suggestiveness, but still require validation by comparison with other data about a person.

Probably the most widely used and best validated of the projective techniques is the Rorschach. This is a series of ten plates depicting symmetrical ink blots, some in black and white, some with touches of color, and three all in bright colors. The subject is asked to tell what he sees in each blot or what the blot makes him think of. This was devised by Hermann Rorschach (23), a Swiss psychiatrist, and the results published in 1921 after some ten or more years of experimentation with the responses of different types of mentally disordered patients. Rorschach paid little attention to the content of the response, but drew conclusions from the formal characteristics of the answers. He found that different psychiatric types give responses having distinctive characteristics and from these findings he was able to develop his experimental method into a test of the nature of personality structure. The Rorschach method is now recognized as having positive clinical value. Rorschach's experimental findings are clearcut enough that certain of the major differences can be interpreted blindly with considerable confidence. Since the Rorschach is treated in a separate article in the encyclopedia, it is not described further here.

Another test which is now recognized as a standard instrument is the Thematic Apperception Test (already referred to in this article) devised by H. A. Murray and Christine Morgan (19). This might be called the picture-story method for in it the subject is presented one by one with a series of pictures, and is asked to make up a story which the picture suggests. After looking at the picture the subject is asked to tell a story which would relate the events leading up to the situation depicted, to tell what the characters in the picture are saying, thinking, or feeling, and then to tell how it will turn out. In the present series twenty stories are obtained—ten each on two

separate days. The stories which this method yields are valuable particularly for interpretation that may be made of their content. The subject projects his own impulses, trends, wishes, anxieties and moods into the characters with which he identifies himself. These trends often are not those which find expression in the subject's contacts with the world and which give him his personality and reputation, but are those which are hidden and repressed. But these trends may find expression in stressful situations or in disguised ways through various mechanisms. Interpretations of the Thematic Apperception Test cannot be reduced to set rules and formulae, but must depend on the intuition and insight of the examiner and only in conjunction with other facts concerning the life history and personality of the subject.

Other projective techniques are still in an experimental stage and will not be mentioned here. Naturally such techniques as painting, finger-painting, drawing, clay modeling, and free play with toys do not require prepared material, and are not dignified by special titles.

Projective techniques represent a powerful method of investigating the motives and personality trends of an individual, particularly those which lend themselves to dynamic interpretation.

PROPAGANDA.—The term "propaganda" came into prominence as a result of the war years, 1914-1918, but propaganda as a technique of influencing behavior by the manipulation of words and other symbols has a long history. Signs have been discovered on the walls of ancient cities which are essentially political appeals. In the seventeenth century, Pope Urban VIII established the *Congregatio de propaganda fide* which was to be concerned with the training of missionary workers and the spread of the Roman Catholic faith. During the Civil War the United States Government sent many agents to England to plead the Union cause. It was World War I, however, which served to make most Americans familiar with the word propaganda and to cause them to associate with it a feeling of evil and sinister intent.

The tendency to consider propaganda as something basically "bad" has led to many attempts to differentiate between propaganda and education. Doob (1935) insists that the distinction is one as to whether or not the same end result would have been achieved with or without the use of suggestion. If suggestion is necessary to achieve the goal then propaganda is involved; if the same goal would have been achieved without the use of suggestion, then this is called education. LaPiere (1935) attempts to make a distinction between propaganda and education by stating that the efforts of a majority to convince a minority might be called education, whereas the efforts of a minority to convert a majority might be called

propaganda. Many other attempts have been made to separate propaganda and education, either on the basis of the end result achieved or on the basis of the methods involved. Despite these many efforts, however, propaganda and education, from a psychological viewpoint, seem to be closely related.

Both propaganda and education are primarily concerned with the use of symbols as means of influencing behavior. More technically, in a psychological sense, propaganda is the systematic attempt to manipulate a stimulus field in such a manner as to control the psychological structures of groups of individuals and thus to control their actions. This definition, however, must be understood in terms of its component parts.

"To manipulate a stimulus field" means to structure the stimulus field so that it tends to be perceived in accordance with the desires of the propagandist. "The stimulus field" may consist of events, objects, conditions, and—what is more important for propaganda—symbols representing these things. "To control the psychological structures" means to arouse, weaken, reinforce, bring about a new integration, or to modify the psychological structures. The term "psychological structures" refers to the determining tendencies, attitudes, beliefs, values, opinions, and stereotypes, which have been incorporated within the individual as a result of previous experience and past learning. "Groups of individuals" may consist of national, occupational, political, religious, or any other potential groupings. By so influencing the attitudes and opinions of these groups, the propagandist hopes that their behavior may be directed into desired channels. The intention may be to inhibit certain patterns of behavior or to evoke others. The actions themselves may consist of such patterns as obedience to law and authority, voting, rioting, or buying.

Accepting the definition of propaganda proposed, there is no basic difference between propaganda and education. Attempts to characterize propaganda as emotional and education as rational are not practical when, as a matter of fact, much propaganda is rational and much education is emotional. To say that education is no longer education but is propaganda when it becomes emotional is to draw a fine theoretical distinction that has little relationship to reality.

It is sometimes said that education is concerned with facts and that propaganda is not. This is simply drawing another distinction that does not hold in practice. Education, like propaganda, is concerned not just with facts, but with facts in a context. As Erika Mann demonstrates in *School for Barbarians* (1938) even arithmetic as taught in the German schools under the Nazi regime contributed to the "Nazification" of school children. Ellis Freeman (1936) has made a similar point in connection with the teaching of elementary arithmetic in America. School children in the southern states do not get the same historical picture of the Civil War as children in the northern states. And American school children do not get the same perspective of the American Revolution as do children in England.

Facts alone do not result in a well balanced education, nor do facts alone result in efficient propaganda. Propaganda, like education, includes the interpretation of facts in order to bring out their significance and in such a way as to influence beliefs and behavior.

In the early days of World War II, Elmer Davis, Director of the United States Office of War Information, made the following statement concerning America's propaganda activities: "To the Allied countries and the occupied countries we have to tell the story of what American is doing and what America is getting ready to do, to tell them the story of American production and to make them realize that we are going to win. . . . And to the enemy countries we have to keep telling that same story until they too realize they must believe it—that we are going to win." The point which is implied in this statement is that no communication is effective as propaganda until it makes people realize something that they didn't think of before or has some other effect on beliefs, opinions, and attitudes. It is obvious that not all facts will be of equal importance in accomplishing this objective. But even "selected" facts must be given the proper interpretation if the maximum propaganda value is to be gained from them.

The propagandist takes an event or set of facts and places upon the event the interpretation that he desires. Or he describes the event in such a way that his interpretation will be accepted. If the event cannot be treated in the desired fashion, then the propagandist may

choose to ignore it completely. The techniques which he may make use of include: (1) *distortion* or twisting the facts to get across his point; (2) *suppression* or the failure to touch upon the event at all; (3) *fabrication* or the description of some imaginary event; (4) *diversion* or the placing of emphasis upon one event in order to distract attention from another; (5) *selection* or the use of only limited aspects of the event with neglect of others equally important; (6) *simplification* or reducing the complexities of a situation to a simple formula.

The Institute of Propaganda Analysis has listed seven devices which are commonly used in propaganda activities: (1) *name-calling* which involves labeling an issue or an opponent with a "bad" name in an attempt to arouse negative feeling tone; (2) *glittering generalities* or the identification of a program with "virtue" words such as "liberty" or "freedom" in an attempt to arouse positive feeling tone; (3) *transfer* which is the attempt to carry over the prestige of some authority or institution to the ideas of the propagandist; (4) *testimonial* or the quoting of approval of the propagandist's ideas by persons in positions of prestige or authority; (5) *plain folks* in which the impression is conveyed that the propagandist's ideas have their origin in the masses; (6) *card stacking* which is the use of deception and false statements; (7) *band wagon* which is an attempt to give the impression that the program is being taken up by the vast majority.

It is obvious that many of the so-called propaganda devices listed above can be subsumed under the general principles of association or conditioning. The principles of association are, as a matter of fact, basic to all propaganda. The propagandist can only hope to control behavior by using stimuli, usually words, which will arouse in the individuals being propagandized the associations which the propagandist desires. The propagandist must at all times capitalize upon the existing psychological structures in the group being subjected to his propaganda.

The use of propaganda during time of war and as an aid to the military defeat of a country is technically known as "psychological warfare." Psychological warfare, like propaganda, is not new. It was used by Genghis Khan who, among other things, sent agents ahead of his

army to spread rumors that the Mongol hordes were coming, spreading death and destruction to all who opposed them. Despite the fact that the Khan's forces were in many instances outnumbered, the rumors often proved effective in producing submission without actual fighting. The Khan was using symbols as a means of influencing behavior.

The difference between ancient and modern psychological warfare rests largely in the development of modern means of communication, radio in particular, which can be used to spread propaganda. World War II saw the use of government-sponsored radio broadcasts to other countries for propaganda purposes. But in addition to these openly sponsored broadcasts by various governments, World War II was also instrumental in developing the "clandestine" or "secret" radio station. Clandestine stations purport to be located inside of some country other than the actual country from which they are broadcasting. Germany, for example, sponsored several stations located in Europe but which claimed to be located in England and which the Germans pretended were operated by dissident elements within England. Clandestine stations are used to spread rumors, lies, slander, and all manner of material that official stations cannot afford to touch. Official stations commit their governments publicly. If they issue lies and misinformation the reputation of the government sponsoring them suffers. Clandestine stations can afford to be irresponsible since they pretend to be located inside of the country attacked. If they prove unreliable no harm is done the actual sponsor.

In World War I leaflets were used as means of spreading propaganda to combat troops. These leaflets usually played upon the attitudes of the enemy in an attempt to get him to surrender. They often promised good food and treatment if he would surrender and death and destruction if he did not. Trench mortars were used to shoot bundles of leaflets across enemy lines. Balloons with timed fire fuses for the release of packages of leaflets were set off with favorable winds. Planes were used to some extent also for dropping leaflets.

In World War II, the bombing plane with its long range flights and carrying capacity was the modern method of leaflet distribution. Leaflets were printed in the form of wrappers for

small cakes of soap and dropped to enemy civilians. Messages were also printed on match covers, and on wrappers for needles, thread, shoe-laces, candy, and other useful articles. British and American bombers dropped thousands of small newspapers printed in many different languages over Europe. These small papers when rolled approximated the size of a cigarette. Fine print enabled them to carry about 10,000 words. The papers were put to press just before an air mission in order to include the latest news. Special editions covering the speeches of Prime Minister Churchill and President Roosevelt were published and distributed. Decisions reached at Teheran and Yalta by the Allied powers were rapidly made known to Germany in the same fashion.

Bruntz (1938) has attempted to evaluate the effectiveness of Allied propaganda in the defeat of Germany in World War I and the importance which the Germans themselves attached to propaganda as a factor in their defeat is attested to by the documented reports in *German Psychological Warfare* (1941). Although no complete report has yet been made public concerning the effectiveness of Allied propaganda during World War II, its value has been publicly acknowledged by many Allied military officers.

During the interval between the two wars, social psychologists have carried on extensive research on changes in attitude as a result of propaganda. In selecting but a few of the many studies in this field for mention, the classical work of Peterson and Thurstone (1933) on changes in attitudes of children as a result of viewing motion pictures cannot be overlooked. Groups of children were tested by means of attitude scales before and after viewing pictures designed to change their attitudes. In many instances very definite shifts occurred between the two tests. Other investigators have concerned themselves with the effectiveness of speeches, printed material, radio talks, discussions, and so forth upon changes in attitudes. A study by Annis and Meier (1934) has demonstrated that it is possible to create favorable or unfavorable attitudes toward an unfamiliar individual by means of "planted" editorial comment. Hartmann (1936), in a field experiment on the effectiveness of rational versus emotional appeals, reaches the conclusion that emotional propaganda is much more effective than ra-

tional. But whether this generalization would hold with groups at all intellectual levels is not known.

Despite all of the research in the field of propaganda, little effort has been directed toward a systematization of this research in terms of general principles and rules. Political scientists have been largely interested in historical descriptions of various propaganda campaigns and psychologists have perhaps been too much interested in the measurable change in attitudes as a result of propaganda. What is needed now is an analysis of the basic psychological processes involved in attitude change. Some starts have been made in this direction by Doob (1935), Newcomb (1943), and others, but there still remains much to be done.

PSEUDOPSYCHOLOGY.—The term covers a number of unscientific methods of judging personal traits and vocational abilities and

predicting life events; it also includes outpourings in the form of lecture series and sundry publications purporting to be sound psychology but in reality the work of uninformed persons.

Palnistry, or *chiromancy*, is the oldest of the methods. No one knows when palm-reading first began, but in China it is said to have been in vogue at least three thousand years before Christ, and the oldest Greek writings refer to it as a familiar practice. At present it is well known in most parts of the world and extensively used in China, India, Syria, Egypt, and Arabia. The Chinese also used *pedomancy*, or divination from observation of the soles of the feet. In both *palnistry* and *pedomancy* the characteristics of the hands and feet, especially the creases and muscular mounds of the palms and soles, are believed to have specific meaning. In the past there were often differences of opinion as to interpretation, but at present most *chiromantic* authorities agree rather closely. For instance, the formation and size of the "mountain of Venus," the muscular swelling at the base of the thumb, is commonly supposed to indicate the kind and degree of love, i.e., whether the individual is loving, lustful, or charitably-minded, and to what extent. The line at the base of "Venus" is the "line of life"; its length, interruptions, terminations, etc., are believed to reveal the course of life. There are hundreds of lines, crosses, triangles, swellings, etc., which have been interpreted. The general shape of the hand, its dryness or moisture, softness or hardness, and so on, are also sources of information as to personal traits and the future.

To those who understand anatomy these explanations are absurd. The lines and swellings of the hands and feet are actually due to mechanical necessity. The thick skin of the palm must necessarily be creased so that the hand can bend to grasp; the formation of the folds depends on the arrangement of fibrillar tissue which binds the skin in place. The mountain of Venus is merely a muscle which can be developed through exercise like muscles in general, and its size cannot conceivably have any correlation whatsoever with love, lust, or charity. There is no valid reason for supposing that any of the lines and prominences should be explained in the fanciful fashion of *palnistry* of the usual type. However, Dr. Charlotte Wolff, in her book *The Human Hand* (1943), tries to build a case for an improved kind of

palnistry based on her theory that characteristics of the hand disclose operations of the brain and other physiological activities. Josef Ranald takes a rather similar position. Neither of these authors uses the rigorous experimental procedure of academic psychologists in the United States. In the attempt to make *palnistry* scientifically reputable, it is sometimes subdivided into *chiromancy*, or foretelling the future, and *chiroscopy*, the interpretive science of the hand.

Physiognomy is the art of judging mental traits from the body lineaments and other physical characteristics, especially those of the face. It may also include predictions regarding vocation and general fortune-telling from appearance. In this field a great deal of unverified opinion has been interspersed more recently with scientific investigation. The practice of *physiognomy* is a very old one, still thoroughly supported in literature and popular belief. Persistent crude attempts to read character from form and feature are made by many persons. Some take advantage of human credulity to promote financially profitable "systems" which claim to discover vocational abilities. Popular *physiognomy* leans heavily on the common tendency to see analogies and draw unwarranted conclusions therefrom. The features are generally taken singly for interpretation. A prominent chin brings to mind prominence of such a vigorous trait as will power; a bulldog-like expression suggests the tenacity characteristic of that animal; a coarse skin must mean coarseness of nature, etc., etc. Certain other factors also obviously operate in diagnosis. For instance, what is known psychologically as "set" is often present. If one believes and expects blondes to be "changeable" and "variety-loving," as the *physiognomist's* manual says they are, it is much easier to discover these traits than if there is no such set, or a different attitude altogether. Again, there is a strong human propensity toward remembering only those instances when the similarity is substantiated and overlooking all disagreements.

There have been a variety of commercial systems of *physiognomy* on the market. In 1922 Kornhauser and Jackson circulated a questionnaire among a hundred industrial employment managers and insurance agency managers inquiring whether or not they used systems of this kind. About 6 per cent were found to do

so. Probably such systems are less used than formerly, but one of the best known of those popular in 1922 is still listed in a bookseller's "Success Catalog" for 1945. Experimental investigations of the methods always show the latter to be untrustworthy. In one study, Paterson and Ludgate submitted to about one hundred persons lists of traits supposed to be characteristic of blondes and brunettes. The judges, who were unfamiliar with the claims made by promoters of the system, were asked to think of two decidedly blonde persons and of two strongly brunette ones. Each was to be rated plus or minus on every trait, according as to whether or not it was possessed by the individual. There were wide discrepancies in results. Blondes often had "brunette" traits, and brunettes had the characteristics of blondes. Results were varied but there were even some reversals in ratio. For example, 84 per cent of the brunettes were judged "positive," a supposedly "blonde" characteristic, as against only 81 per cent of the blondes; and 64 per cent of the brunettes had the "blonde" trait of dynamism, with 63 per cent of the blondes so rated. Cleeton and Knight undertook to investigate the relationship between eight character traits and the physical features said to be indicative in several popular systems of physiognomy. They made a total of 201 careful measurements on thirty persons. They then compared their findings with the judgments of intimate associates of the subjects and also with those of strangers. There was no correlation at all in the former case and a practically zero one in the latter.

Yet it must be admitted that the commercial physiognomist and many other nonscientific observers are frequently fairly correct in their conclusions. Obviously there are other clues than skin color and texture, size and shape of features, etc. Investigation shows that these other clues lie in such sources as expression, manner, way of speaking, dress, and frequently the unanalyzed total impression conveyed. The confident individual is likely to have an air of confidence implicit in many details of appearance. The optimistic person probably has an expression of cheerfulness and optimism. The very successful man radiates success because his repeatedly successful actions have resulted in the habitually energetic, commanding bearing we associate with success. In like manner the

facial muscles of those who are constantly gloomy may settle into fixed lines of depression. Or kindness may seem to shine from the eyes of the kindly, though in reality the eyes do not change. It is the eyelids and the muscles of the face which are capable of being molded by habit. Psychologists have given a good deal of study to the kind of behavior they call "expressive movement," like facial changes, gait, and gesture. Word pronunciation, vocabulary, quickness or slowness of response, kind of clothing, make-up, appearance of hands, manners or lack of them, are more details which give information about a person's past, present, and future. From time immemorial fortune-tellers of all kinds have, consciously or unconsciously, built their business on such signs.

In predicting vocation there are certain other factors which aid the forecaster. Most persons can succeed not only in one field but in several, a fact which greatly increases the possibilities of correct prognostication. Then, too, the individual's likes and dislikes, easily ascertained in conversation, are indicative of his abilities, for the accredited psychologist has found some correlation there. Furthermore, advice offered by a person posing as an expert may produce a helpful instigating "set" leading to success. In any event, as has been said before, human nature is such that only those predictions which are fulfilled are likely to be remembered and reported to others.

Further light is thrown on the subject by attempts on the part of genuine scientists to relate mental traits to general type of body form and structure rather than to specific features. This approach goes back even to Hippocrates (d. 377 B.C.), the first lay physician of Greece, who distinguished two fundamental physical types, the *apoplectic habitus* with short, stocky body, and the *phthisic habitus* of long, thin form. These are the prototypes of the *pyknic* (compact) and *asthenic* (without strength) types described by Kretschmer, the German psychiatrist, in 1921. He observed that his manic-depressive patients generally fell into the former classification; the schizophrenics, on the other hand, were likely to be "asthenic," or perhaps "athletic," a third grouping descriptive of those more muscular than stout or thin. By analogy normal persons were said to be of at least two kinds of temperament, "cycloid" and "schizoid." In the pathological field some cor-

roboration of Kretschmer's theory has come from the work of Wertheimer and Hesketh, Farr, and Mohr and Gundlach. In the last quarter of the nineteenth century Lombroso in Italy advanced the hypothesis that criminals were likely to exhibit "stigmata," that is, physical abnormalities which were evidence of degeneracy or atavism. Goring later upset Lombroso's observational claims by taking precise anthropometric measures of a large number of English criminals and obtaining mostly negative results. But Hooton at Harvard, using criteria that appear to pertain more to general body type, has recently found statistically valid relationship between criminality and physique in American convicts. The Italian anthropometrists under Viola's leadership have recognized three morphological types, the *macrosplanchnic*, the *normosplanchnic*, and the *microsplanchnic*, a trichotomy suggesting Kretschmer's. One of Viola's pupils, Naccarati, who came to the United States, endeavored to correlate intelligence with an index of physique derived from ten body measurements. His studies, in 1921, of several groups of Columbia University students showed positive correlations but too low to be significant. Many similar attempts were made by others to correlate intelligence and single parts of body structure, like head size and face length, but again nothing better than low positive correlations were secured. D. G. Paterson in *Physique and Intellect* (1930) has expressed the point of view of many American psychologists who have seriously questioned the concept of correlation between physique and mentality at least in normal persons.

The most careful study of body types yet made is the recent work of W. H. Sheldon at the University of Chicago and Harvard. He first found that the general factor of bigness with horizontal breadth offered a low negative correlation with intelligence test scores and "emotional excitability"; and a low positive correlation with the social traits of aggressiveness, leadership, and sociability. Subsequently he obtained very exact measurements from standardized photographs of four thousand undergraduate male college students, in front, back, and side view. He identified three extremes of physique, and was thus able to derive his terms for the essential components of form: (1) *endomorphism* (soft roundness predominating); (2) *mesomorphism* (muscle, bone, and

connective tissue outstanding); and (3) *ectomorphism* (linearity and fragility conspicuous). This classification corresponds roughly to Kretschmer's, but seems to represent distinctly more accurate analysis and delineation. Sheldon seeks to avoid both confusion and rigidity in typing by proposing, in his *The Varieties of Human Physique* (1940), a seven-point scale for "somatotyping" individuals on each of the three components; and he emphasizes the concept of the continuum rather than fixed typical point.

He has identified corresponding types of temperament and devised a rating scale on the basis of extensive interviewing and observation, and use of a variation of factor-analysis technique. *Visceratonia* is said to be the correlate of endomorphism and is "roughly identifiable with love of comfort, relaxation, sociability, conviviality, and sometimes with gluttony. . . . *Somatotonia* is the motivational pattern dominated by the will to exertion, exercise, and vigorous self-expression. . . . *Cerebrotonia* refers to the attentional and inhibitory aspect of temperament. In the economy of the cerebrotonic individual the sensory and central nervous systems appear to play dominant roles." In *The Varieties of Temperament* (1942), Sheldon describes his seven-point scale for rating sixty traits, twenty under each of the types. Sample items are as follows: (1) for visceratonia, "relaxation in posture and movement," "love of physical comfort," "evenness of emotional flow"; (2) for somatotonia, "need and enjoyment of exercise," "competitive aggressiveness," "overmaturity of appearance"; and (3) for cerebrotonia, "overly fast reactions," "love of privacy," "self-conscious motility of the eyes and face." To obtain "a full constitutional analysis" there should be "not less than twenty analytic interviews" over a period of "at least a year." However, for special purposes Sheldon also suggests shortened procedures, even including a single twenty-minute interview. Scrutiny of the complete scale and directions for rating shows that conclusions are to be based largely on present appearance and behavior and the subject's report of his past activities. The medical history as well as the life history is always taken, and special topics investigated or extra tests given when the need is indicated. The Wisconsin Scale of Radicalism and Conservatism and the Chicago Scale of Mental Growth have been used. With the abbreviated twenty-minute form the examiner observes some sim-

each is located in a specific part of the brain surface; (4) size of such regions correlates with amount of the concomitant faculty; (5) examination of the outer surface of the skull makes clear how much of each mental power an individual possesses. The phrenologist's chart in final form locates thirty-six faculties. The "propensities" are: amateness, philoprogenitiveness, concentrativeness, adhesiveness, combativeness, destructiveness, alimentiveness, secretiveness, acquisitiveness, constructiveness, and vivativeness. The "lower sentiments" are self-esteem, love of approbation, and cautiousness. And the "superior sentiments" comprise benevolence, veneration, conscientiousness, firmness, hope, wonder, ideality, wit, and imitation. The "perceptive faculties" consist of individuality, form, size, weight, color, locality, number, order, eventuality, time, and language. Completing the list are the "reflective faculties" of comparison and causality.

Psychologists and physiologists certainly agree with the general thought of the first of the phrenologist's postulates, and are convinced that the brain is at least the major correlate of the mind. But the other four principles are no longer accepted by science. What completely upset Gall's theory of localization of faculties was the discovery that there is a different kind of localization in the brain. During the Franco-Prussian War an army surgeon, Fritsch, noticed that electrical stimulation of a brain exposed through injury resulted in muscular movement. It was found that such movements were specifically related to certain brain areas, e.g., if just the right portions of the brain at the top of the head were touched or stimulated electrically, jerking of the legs would result. The various kinds of sensations were also discovered to be localized. For instance, we now know that the base of the brain at the rear (where Gall put "philoprogenitiveness," or love of children) is concerned with vision; and the area around the ears (Gall's place for destructiveness), with hearing. It should be added that there is still question as to the degree of localization of function indicated by the evidence. Since many parts of the cerebrum must be involved during much of our thinking, psychologists often prefer to say that the brain can be thought of as operating habitually in wide-spreading patterns of neural energy. There is no possibility of the

existence of specific places in the brain where the Gallian faculties reside. Many of these are in fact very complex, and necessarily lead to ways of behaving which depend on operation of much of the brain; others seem to be too circumscribed to fit the physiological facts.

Another argument against the phrenologist's localization of faculties comes from studies of the results of destruction of parts of the brain through injury. Such losses show no correspondence with the Gallian disposition of traits. Furthermore, the phrenologist's idea of size as a sign of mental development is baseless. Some individuals with unusually large heads are feeble-minded because the skull contains an inadequate amount of brains and an over-supply of cerebro-spinal fluid. In such cases certain parts of the cranium are extraordinarily well developed, but there is no analogous increase in the faculty supposed to be there.

Phrenology is now not entirely defunct, but has been taken over by fortune-tellers, sham psychologists, and other persons of exceedingly dubious reputation. A report of one individual of this description comes from a soldier at a large army camp of the Second World War. The phrenologist in question made very successful efforts to attract the patronage of the draftees, advertising himself unambiguously as a "bumpologist."

Graphology is the art or science of discerning characteristics of personality from handwriting. In popular judgment in the United States it has been accepted with the same eager credulity evinced toward palmistry, physiognomy, and phrenology. Similarly there are "practical applied graphologists" who promise—for a financial consideration—expert guidance in personality development, vocational and marital selection, and, in fact, in practically all human problems, even including elimination of war! It is little wonder that accredited psychologists in this country are apt to regard graphology as the province of quacks and scientifically worthless. In Europe, on the other hand, the situation is different. There scholarly interest in the subject and legitimate investigation have flourished.

It is hard to say when handwriting as a means of personality diagnosis first attracted attention. Toward the middle of the seventeenth century Camillo Baldo in Italy published his treatise on graphology. The modern period can

be said to have been initiated around 1860 by the Abbé Michon in France. He and his pupils tried to build up a trustworthy set of criteria by looking for similar characteristics in the writing of persons possessing a certain trait to a marked degree. As a result of their studies what is known as the "sign" method developed. A "sign" is a detail of script, such as a's open at the top or high capital letters. An elaborate series of "signs" was finally recognized. Eventually a number of American psychologists began to evaluate the claims of graphologists through experimental test, but with largely negative results. June Downey in 1919 called attention to fallacies of unsupported analogy. For instance, without due validation disconnected writing was declared to be a manifestation of disconnected thinking, and long upward strokes, of "upward" (idealistic) inclinations.

In the same year Hull and Montgomery reported a study of the handwriting of seventeen college fraternity brothers. The signs, which were measured microscopically, included upward slant in alignment, fineness of line, lateral narrowness of m's and n's, length and heaviness of t-bars, and closed a's and o's. The subjects were asked to rate each other on the traits supposed to correspond to the "signs," i.e., on ambition, pride, bashfulness, force, perseverance, and reserve. The correlations turned out to be either negative or very low, the average of all correlations being $-.016$, or almost zero. This overwhelmingly adverse finding has been much quoted by psychologists and other scientists in the United States, many of whom have little other information on graphology. However, Downey and Gordon Allport (writing in 1933 in collaboration with British-born Philip Vernon) upheld the growing European belief that handwriting was a significant form of expressive behavior which, if properly studied and interpreted, would be a sound source of knowledge concerning personality. In *Studies in Expressive Movement* Allport and Vernon raise objections to the study of Hull and Montgomery. The findings of the latter regarding "signs" are criticized as follows: "Practically no graphologist at the present time, certainly not the leading authorities, claims any fixed and invariable significance for any of these 'signs.' Although borrowing in part from the signs listed by Crépiaux-Jamin, the investigators

omitted entirely his doctrine of 'resultants.' No attempt was made to balance and synthesize the signs or to work with the form-quality of the whole script."

This criticism suggests a position different from that held by the earlier graphologists. Further quotation from the same authors will make clearer the new viewpoint: "Most of the experiments devised by skeptical psychologists, who seek correlation between specific details of script and specific traits, are foredoomed to negative results. If we are to attain the most adequate validation, *the script as a whole and the personality as a whole must somehow be compared.* . . . Some experts, notably Saudek, incline to base their interpretations on a scientific analysis of the numerous factors involved in handwriting. Others rely chiefly on general impressions and *Formniveau* [total impression]."

As Allport and Vernon indicate, the era of signs has been almost completely replaced by one in which general factors and interrelationships of script are the basis for diagnosis. European inquiry into the subject of graphology has continued steadily. There is a large and increasing body of information brought forward by authorities. After Michon the distinguished psychologists Wilhelm Preyer and Alfred Binet were among the earlier authors to produce careful studies in the field. Germany and France have had many exponents of the subject. In Germany, Klages, Meyer, and Bobertag are some of the well-known twentieth-century writers on graphology; in France, Crépiaux-Jamin, a pupil of Binet, probably has the widest reputation. Saudek, writing in both German and English, has been very active in graphological investigation. There has been appreciable interest in it in England and also in Holland. Study of handwriting has proceeded along a number of lines. Koester, de Fursac, Hirt, and Gross found characteristic penmanship in the different mental diseases. Couvé, von Kügelgen, and Seesemann have reported satisfactory vocational diagnosis through script in the industrial and personnel fields, though critics point to some errors in validation. Two important methods of application have emerged, viz., (1) the *sorting* method and (2) the *matching* procedure. An example of the first is Saudek's sorting of unfamiliar handwriting samples by detecting through his own criteria which of the

writers were honest and which dishonest. The second method has several variations, but usually the judges "match" specimens of penmanship (or graphological analyses) with known persons or with personality descriptions. By any method it is found that in general the graphologist is a more successful judge than the inexperienced individual, though results are far from perfect with the former and show considerable variation in accuracy. Furthermore, entirely untrained individuals are sometimes highly proficient.

Handwriting is looked upon by authorities as expressive behavior like gesture, gait, or facial expression. Allport and Vernon vigorously testify to the graphologist's belief that expressive activities in general are related to each other in well-patterned association, and that all such movement is congruent with personality traits. These authors have performed experiments proving "inter-muscle consistency," thus supporting the previous demonstrations of Preyer and Saudek that a person's writing is much the same whether it be executed by his right hand, left hand, toes, or mouth. The uniqueness of basic quality in handwriting is further evidenced by hereditary resemblances in writing and distinctive variations in the script of individuals reared in the same school of penmanship. Some graphologists analyze the movements of the hands and variations in pressure and speed. Many factors such as age of the writer, the penmanship system he has been taught, his health and present mood have been found to complicate determination of personality from handwriting. American psychologists have contributed some excellent studies of the psychology of graphic movement, which may help toward a firmer foundation for graphology. But details as to the research aspects of the subject are beyond the scope of this article. There is little doubt that handwriting is genuinely characteristic of the individual, and that it is a form of expressive behavior, though the precise manner of expression is not yet entirely clear.

Recent immigration has given American psychologists close-range acquaintance with the concepts and work of a number of European graphologists of the newer school. Eliasberg's interpretation of the handwriting of Hitler, Goering, Goebbels, and other political figures appeared in *The Journal of Psychology*, Octo-

ber, 1943. Marseille has been employed by Spiegel's, Chicago mail-order house, to determine through examination of handwriting whether or not prospective customers are "good risks." In their book *Handwriting Analysis* (1942), Mrs. Thea Stein Lewinson, from Berlin and Paris, and Joseph Zubin, whose doctorate is from Columbia, have attempted to put graphology on a genuinely scientific basis by providing a statistical method for checking results. But in spite of these and other efforts American psychologists for the most part do not show much interest in the subject and are not well informed about it. They are repelled by the nonquantitative, "intuitive" approach and the inexactness of terminology so frequent in graphological studies. Moreover, the prevalence of much quackery in this country obscures possibilities in graphology. To the critically minded it still seems at best more of an art than a science at the present time.

Spurious Psychology. Between 1920 and 1930 a distinctly unauthoritative kind of psychology was at the height of its popularity. D. H. Yates describes this movement in *Psychological Racketeers* as taking two general forms, (1) the lecture series and (2) published material of many kinds, conspicuously "systems of applied psychology." The author or itinerant lecturer was a person untrained in scientific psychology whose chief aim was to capitalize on current enthusiasm for psychology as popularly understood. Before the tuitional lecture series came abundant advertising and several free lectures replete with tantalizing hints of what was to follow. Course fees ranged from ten to fifty dollars per person. Since the "psychologist" generally stayed less than two weeks in any one town and a good spellbinder could attract a large audience, the proceeds must sometimes have been enormous. These were augmented through side offerings such as extra courses or lectures, and books and pamphlets by the lecturer, or specialties like phrenological examinations, handwriting analyses, and vocational diagnoses through physiognomy of the commercial variety. The published "systems" provided another medium for "applied psychology," and were promoted in correspondence courses or book form. Here again prices were high. However, it was always asserted that "rates were greatly reduced"; they were reduced still further if the prospective purchaser

was excessively recalcitrant in responding to numerous letters of advertisement. Yates found upon investigation that there was considerable use of unauthorized endorsement.

The vendors of this kind of psychology exhibited no knowledge of academic psychology or psychologists. In the lectures there was almost total absence of allusion to any accredited psychologists. In all Yates' extensive collection of literature on "applied psychology," she found only an occasional superficial reference to Freud or to William James. The writer or lecturer concocted a mixture of ideas borrowed from Christian Science, Coué, Yoga, other "applied psychologists," and his own imagination, which was sometimes very wild indeed. Unbelievably bizarre statements and fantastic promises appealed to the uninformed who wanted "health, happiness, and success." These self-styled "authorities" obviously set out to cater to fundamental human desires, and their stock slogan was "the power of thought." Their unmistakable objective was money for themselves. A very few were probably self-deluded but well-intentioned persons "not above indulging in a certain amount of hocus-pocus and highly colored assertion to help themselves along," as Yates puts it. At best, these people offered inspiration, encouragement, and some good practical advice. More often they foisted upon the public dangerously misleading notions regarding psychology, medical science, and science in general. They misdirected people vocationally and personally, often causing tragic failure after the arousal of false hopes.

Their type of spurious psychology lessened but did not disappear during depression and war years. A few of the very same itinerant "psychologists" have continued to lecture, though their field of operation was severely limited during the period of travel restriction. Courses and systems advertised by mail have much the same teachings as formerly, but blossom with ever new names, "The Invisible Power League," the "Effective Thinking Foundation," and the "Religion of the Stars" will now enlighten the world. The current fad is certainly astrology. During the severe paper shortage newsstands no longer displayed literature on "applied psychology," but publications on astrology have constantly increased. The contents of these astrological periodicals and horoscopes is a serious reflection on national

intelligence, since astrology is a primitive and thoroughly unscientific attempt to relate the stars to human affairs.

PSYCHODRAMA.—*Origin and Meaning of Psychodrama.* The first theatre for the psychodrama was founded by Dr. J. L. Moreno in Vienna, in the year 1922. It was called the "stegreif-theater," a German word which can be translated in different ways—"being stirred up," "warming up quickly," "get started," "acting on the spur of the moment." In essence a "stegreif-theater" means a theatre which is dedicated to the spontaneous drama. At that time what concerned Dr. Moreno primarily was the momentary structure of a situation, and how to get the individual started so that he may throw himself into a momentary state. The momentary structure of a situation for spontaneous dramatic purposes, whether suggested by the director or the actor himself, consisted of a situation carefully specified, of a role for the individual actor, and of a number of personified roles by other actors needed to bring the momentary structure to as clear and dramatic an experience as possible—all this to be brought into action on the spur of the moment. Dr. Moreno, being a psychiatrist, developed at the same time, aside from the aesthetic aspect, another aspect of "stegreif," that of the therapeutic—the study and treatment of mental problems by

means of the spontaneous drama. It was in this aspect of development that the momentary "personal" situation of the actor, his private personality, his inner strivings, and his conflicts with people around him became the chief emphasis for diagnosing personality difficulties as well as more severe mental disorders. This information was necessary, moreover, to affect an autonomous treatment and cure. It was realized that he must have charged and tainted all persons and objects of his immediate environment with some aspect of himself, and that this must be traceable in the performance of his bodily and mental functions, in his inner tensions preliminary to these performances, in his gestures and expressions, in the words associated, and in the feelings and movements towards the persons and things with which he lived. Considering the more complex forms of social neurosis, when two, three, or more persons were to be treated simultaneously, the scenes enacted between them became a formidable pattern for treatment. Finally, all the scenes in their remote past and all the remote networks became important from the point of view of a general catharsis of all the people involved. The solution was then the resurrection of the whole psychological drama, or at least of the crucial scenes of the drama, enacted by the same persons in the same situations in which their associations had begun. The new technique, if properly applied, aided the patient to actualize, during the treatment, a situation which was as close as possible to his own life itself. He had to meet the situations in which he acted in life, to dramatize them, to meet situations which he had never faced, which he evaded and feared, but which he might have to meet squarely some day in the future. It was obvious that here was a technique not only valuable as a diagnostic instrument but as a therapeutic one as well, in so far as the subject was able to experience catharsis in the process of unfolding his conflicts, and in finding adequate responses to them on the spur of the moment.

The Stage. The stage¹ consists of a circular

platform of three concentric levels. The levels are representative of levels of psychological processes; for example, the lowest level might be comparable to the conceptual level in the individual's personality; the next level, possibly the visionary level; and the final level, the action level where the realization of the conceptual and visual levels takes place. These different stage levels can also represent different levels of the warming-up process. The catatonic type of personality may take considerable time before he is able to warm up to the point of performance on the third level, whereas the manic type will often literally leap over the first two levels and begin action immediately on the third level. The third level is large enough to accommodate any social situation. The decorative machinations of the conservative stage are absent. Aside from a table, a few chairs, etc., there are no other settings, so that maximum freedom of expression spatially is afforded for the subject and auxiliary egos. The stage consists further of two pillars supporting a balcony upon which the creative ego may realize his imaginary world of grandeur, whether it may be God or the leader of a nation.

A simple system of lights adds to the necessary equipment. They assist in warming the patient up to moods and feelings so that he can more fully throw his psyche into action. If he wishes to portray God in heaven, for example, the blending of red and blue lights gives him the feeling of airiness; all lights out on the stage, except red, give him the feeling of being in hell, where he may want to portray the devil.

The type of audience depends upon the condition of the patient. Often, as in a surgical operation, it is necessary to exclude individuals who are not auxiliary egos and doctors essential in the treatment. If there is an audience, it often consists of individuals chosen by the patient himself, if he does not object to a chance grouping. If he appears to be blocked in his role-playing or hesitant about divulging certain intimacies, he is asked if he wishes to change his original choices. The kind of role in which he functions influences his choices, so that different members of the audience enter and leave the group repeatedly during one session. One or two recorders are always present in order to make stenographic notes of verbalizations, movements, moods, gestures, etc., which the physician needs for analyzing with

¹ The stage described here is the Theatre for Psychodrama at Beacon, N. Y. All other theatres for Psychodrama, for example, the theatres for Psychodrama at St. Elizabeth Hospital, Washington, D. C. (1940), and the one in New York City (1942), are modeled after this design.

the subject after the performance. These records are also necessary for the physician to analyze behavior which suggests need for spontaneity training. At times, gramophone or motion picture records of a session are made and played back to the subject or the audience which was present in the making of them.

The Director. The director, who may be the physician, therapist, or educational director conducts the session, instructs the auxiliary egos, and must be aware of the total situation as it develops. He rarely participates in the action, but stands just off the stage on the side either to encourage the continuance of action if it is lagging or stop the scene at a crucial point for analysis with the subject. Usually, the participants determine the solution themselves.

Important is the director's rapport in his interview with the subject before he goes into action. It is here that the "tele"² phenomenon plays an important part. The stronger the interacting tele is, but particularly the feelings coming from the subject, the better able is the director to warm the subject up to giving the clues for his future action. It is on the basis of these clues that the director explains for the benefit of the auxiliary egos and the subject the problem to be acted out. If there is a negative tele relationship, it is often necessary to eliminate the interview, and place the subject directly on the stage in simple scenes, trusting that the auxiliary egos' intuitive and ingenuous action will draw out the needed information. The subject's dependence, in any case, upon the director is reduced to a minimum, and great reliance is placed upon the subject's reaching his catharsis through the aid of the auxiliary egos. The subject may reject the help of all auxiliary egos; then he acts in all roles himself. If the subject refuses to begin action in any of the problems revealed in the interview, the director suggests a plot not obviously related to the problem, thus leading the subject gradually into the crucial issue. Or the subject may choose his own plot, and use this as a warming-up starter for the subsequent plots to be suggested by the director. If he still resists, the auxiliary ego takes the part of the subject, who becomes a part of the audience. After the

performance, or during it, he is asked if the portrayal of himself is accurate and if he would like to come up on the stage and correct any inaccuracies. This portrayal of the subject by an auxiliary ego is called the *mirror technique*. All of these procedures necessitate the director's awareness of which ideas are central throughout the scenes. He must likewise be cautious of introducing sensitive problems too soon. It is not the director's intention to encourage sheer emotional and impulsive outbursts, but rather to gain as much "sane" responsiveness as possible in simple routine life situations leading up to that point where the subject breaks and refuses to face his situation. This is the director's clue for shrewd construction of new psychodramatic scenes which aim either directly or indirectly at the withheld conflict.

There are two kinds of actor catharsis: (a) action catharsis, achieved in the process of acting out conflicts, (b) post-action catharsis, acquired through the director's interview and analysis after the scene has ended.

Auxiliary Egos. An auxiliary ego is a person whose function is to live through the subjectivity of the subject and identify himself with all the patient's expressions as far as organic limitations allow. He must take the roles of the absentee members of the subject's network of interpersonal relations. The auxiliary ego usually does not know the persons he is to represent. He is dependent upon the clues given to the director before the scenes start and the subject's description to him in front of the audience or in a conference backstage as to how they are to be characterized. Even in symbolic roles (Satan, God, or a judge, etc.) he should act only as suggested by the subject, and interject his own vision of the role as little as possible. A good auxiliary ego will be careful not to overact so as not to overpower the subject to the degree of reducing his spontaneous expression. On the other hand, he must maintain an alertness and force which will stimulate the subject to as complete an unfolding of his psyche as possible. In sum, as with the mother who feeds her child, he must absorb the needs and rhythm of his subject so that he can live through his life situation with him, without being, however, so identical with him that he is unable to reserve a certain portion of his ego for objective evaluation.

The auxiliary ego technique of apparent iden-

² Tele is "a feeling which is projected into distance; the simplest unit of feeling transmitted from one individual to another; see Moreno, J. L., "Who Shall Survive?", 1934, page 432.

tification with the patient's delusions, trying to surround him on the stage (and if possible outside of it) with an atmosphere compatible with his fictitious world, is called the psychodramatic realization technique. The door is wide open which leads to the realization of the imaginary world, but *actual* gratification is not attained. On the contrary, it is important to interpolate resistances gradually from session to session, until the patient is able to accept some of his imaginary world as being untrue. By "some," we mean that it is important that the patient never be entirely disillusioned, but aided in realizing a certain amount of his fantasy world in real situations facing him when he returns to his community.

Audience Function and the Sociodrama.

Therapy is not limited to the subject's performance on the psychodramatic stage; members of the audience are likewise deriving therapeutic value by finding maladjustments of the subject as identical with their own. Naturally, the audience members are considered in the director's analysis of the subject's performance, since they will apply it to their own particular problems. Individual members experience, along with the performers, a warming-up process to the roles which they are enacting on the stage. It is for this reason that the director often questions these members as to how they felt about the performers, whether they were in sympathy with one or the other, or how they would have acted if they were in similar roles. Such an audience reaction shows certain portions of the audience in sympathy with the wife, for example; another portion, for the lover; still another, for the husband. These are called *audience constellations*. In analyzing these constellations still further some members find their problems identical with a private problem, others with a collective problem. The husband may be a Jew, and thereby introduce a social issue—the Jewish problem. There are two kinds of spectator catharsis; (a) individual and (b) collective.

The kind of session which deals with collective problems is called the *sociodrama*. It differs from a psychodramatic session in that the issues presented are of a collective nature, the general roles are lived and experienced in a collective way, and must be portrayed in a collective way. The primary concern of the director is the *group*. The roles which represent collective

ideas and experiences are called *sociodramatic roles* (*the father, the mother, the soldier, etc.*), those representing individual ideas and experiences, *psychodramatic roles* (*a mother, a father, a soldier, etc.*). But we know from experiments that these two forms of role-playing can never be truly separated. Whenever a subject has to portray the role of the husband in an individual and intimate sense, the sociodramatic role of the Jew (referring to the previous example) enters into the picture. Therefore the spectators of a psychodramatic session are affected simultaneously by two phenomena, a personal problem, for instance, a specific husband-wife problem, and an ethical problem, for instance, Jew-gentile. In sum, psychodrama has been defined as a deep-action method dealing with interpersonal relations and private ideologies, and sociodrama, as a deep-action method dealing with inter-group relations and collective ideologies.

Status Nascendi and Warming-up Process. In order for a subject to experience a spontaneous state in which he unfolds the deeper aspects of his personality, he must warm up and act in "statu nascendi." Warming up to these spontaneous states is aroused by various starters. The subject puts body and mind into motion, using body attitudes and mental images which lead to the attainment of the state. This is called the *warming-up process*. The warming-up process can be stimulated by bodily starters (complex physical process in which muscular contractions play a leading role), by mental starters (feelings and images in the subject which are often suggested by another person), and by psychochemical starters (artificial stimulation through alcohol, coffee, for instance). More specifically, the warming-up process making use of physical (body) starters can be seen in the subject who is thrown abruptly into a situation which is novel to him and to which he has to warm up in order to make a rapid adjustment. The study of the somatic reactions to role-taking in "statu nascendi" is called *physiodrama*. There are different degrees of warming up, from a minimum to a maximum, as is exemplified particularly in the patient's gradual approach to the third level of the stage, even though he may warm up quickly and jump immediately to the third level, he may fall far short of reaching his highest degree of warming up when actually there.

Role Theory. Role can be defined as a unit of synthetic experience into which private, social, and cultural elements have merged. It is an interpersonal experience and needs two or more individuals to be actualized. Role definitions which reduce the bearer to one individual are inaccurate. Role definitions which reduce the role-taking process to conditioned responses are a neglect of the importance of the varying intensities of the warming-up process and the degree of spontaneity reached in interpersonal stimulation. The relative unpredictability of the kind of role or the form it will take is due to the *s* factor (spontaneity), which the individual puts forth in a novel situation. Certain role capacities and levels of expression may have been reached by the individual beyond what he ever knew he possessed.

The individual is engaged in the process of role-taking from the moment of birth on, particularly in the roles of the eater and sleeper. We refer to such roles as *psychosomatic* roles. Later on, the child functions in the roles of brother or sister, playmate, daughter or son, etc. These are called *social* roles and function according to cultural standards transmitted through the adult world. *Psychodramatic* roles are often unrealized roles which the individual himself chooses to function in—for example, the role of God or the devil, the role of Santa Claus, or, a boy playing the role of a girl, a little girl playing the role of her mother, etc.

Individuals are tested and trained to determine their range and adequacy of roles, as to whether they are, in role-taking, weak or strong, dominant or recessive, flexible or rigid, slow, fast or overheated. These role characteristics often fluctuate in accord with the role-expectancy of an individual. An auxiliary ego or subject may expect of his partner before entering a psychodramatic scene characteristic role functioning. If this does not meet his expectations, his own role is affected, and any of the above characteristics may then manifest themselves.

Just as we find patterns of acceptance and rejection in interpersonal structures, we are likewise able to find inter-role patterns in which role acceptance and rejection occur. This has been intensively studied in the treatment of marriage problems via psychodrama. The treatment of isolated members in a typical "eternal triangle" in a marriage problem can often re-

sult in wrong solutions, very often left to the discretion of the psychiatrist. However, by treating the problem as an interpersonal unit, placing its members on the stage in typical marital scenes, we see the inter-role patterns emerging as the drama proceeds. It is only during the psychodramatic work that we can study how they take form spontaneously. These inter-role relations are discoveries for the subjects themselves and throw an entirely new light upon understanding their marital difficulties. They discover that there are more roles functioning incompatibly or unfulfilled than those of husband and wife, such as the role of lover, artist-adventurer, career man or woman, etc. They discover further that roles are interdependent, that of deficiency in one role may cause another to be more adequate, or that the psychodramatic training of a deficient role for adequacy may strengthen other roles.

Spontaneity Theory. The backbone, so to speak, of psychodramatic theory is the spontaneity factor. To warm up to a spontaneous state on the spur of the moment in creating or in unfolding the deeper levels of the psyche is a desired achievement in a psychodramatic scene. Spontaneity, broadly considered, is a resourcefulness which integrates, on the spur of the moment, the faculties of the personality to meet a situation. It may be an old situation to which he responds anew or it may be a novel situation. Individuals show various degrees of spontaneity by their variety of responses to a new situation. Studies so far show little or no correlation between spontaneity and intelligence.

It is assumed that the spontaneity factor operates with great intensity and frequency during infancy before intelligence and memory have a chance to predominate. The infant is faced continuously with startling and difficult problems to which he must make a rapid adjustment. Gradually the spontaneous responses become conserved, and as the child grows older, they become a part of memory and intelligence. Memory and intelligence begin to predominate in using conserved patterns as responses to situations and the *s* factor becomes the forgotten function. Spontaneity training is already being used in schools and corrective institutions as a part of educational procedures to encourage the child to continue his spontaneous expressions, to retain them as experiences (not conserves)

to be organized into new responses, which are appropriate for a new situation. He must be trained to develop a plastic adaptation skill, a mobility and flexibility of the self, which is indispensable to a rapidly growing organism, especially in a rapidly changing environment.

Just as we find individuals in need of training because of a low spontaneity factor, we likewise find individuals who have an overflow of spontaneity and a set of conserved patterns which do not click with it. This unbalanced spontaneity is unable to organize conserved patterns into new creative responses. This is observable very often in musicians or actors who find their mediums of expression, the violin or the script of the playwright, a hindrance and a foreign body to their surging feelings of creativity. Often a performance neurosis is the result. A striking example is that of a musician who trembled when playing his violin in a large symphony orchestra. In order to re-educate such people we return them to wild spontaneous expression as a starting point. While on the psychodramatic stage, he was told to try to relax and play his violin without any consideration of musical conserves, freeing himself as much as possible from tensions and images. It was an unorganized chaotic playing. Gradually resistances were introduced such as themes as suggested by the instructor, then, moods of pity and sympathy, so that the feeling of the music carried him; next, he was to give musical interpretations of pantomimes and plays. In this way, he learned gradually to adjust his playing to moods and feelings of other people. As these performances of the people were unpredictable he had to make spontaneous responses to their changes in movements and moods. Here his spontaneity began to become disciplined and orderly. As these resistances continued, he finally reached the point of incorporating the resistances of the musical score now that his feeling of another's creation could envelop him, and now that he had acquired sufficient flexibility in integrating these two factors into his own creative interpretation.

Psychodrama in Relation to Other Diagnostic and Therapeutic Methods. Psychodrama is a deep-action method which differs from psychoanalysis and such projective methods as Rorschach, finger-painting, free association tests, etc., in that it not only explores the same ex-

pressions of personality, but, in addition, the personality in movement and action, and in its social relations. Second, the results from such tests would be far more revealing if a one-way relation of subject and observer in interview methods were to be replaced by the two-way relationship of subject and participant observer functioning as an auxiliary ego in different roles. The therapist views himself as a personality interacting with that of his subject. He takes not only the limited role of the therapist, psychiatrist, or social interviewer. Third, the verbal report methods frustrate a warming up to a maximum spontaneity state due to the restraint of action in space which affords the use of physical starters, i.e., walking, rising or sitting, gestures of hands and arms, etc., in order to warm up to deeper levels of personality expression. In sum, we may say that psychodrama brings the projective reflections into realization through activity. Furthermore, psychodrama appears to be merging the methods of behaviorists and that of the introspectionists by allowing the experiencing and reacting organism to verbalize and *activate* his imaginal content.

Indications and Counterindications. Psychodramatic procedures are especially indicated in minor maladjustments and social conflicts as in family, matrimonial, and employment situations, because of its ideal combination of individual action treatment with group psychotherapy. This explains its low cost, since therapy can be given to large groups of individuals simultaneously.

However, although it is a therapeutic instrument of high flexibility, adaptable to practically every situation, its direction requires high professional skill. Obviously, under unskilled direction, psychodramatic procedures can be harmful to individuals and groups just as the indiscriminate use of a drug. It is especially indicated that in the acute phases of a psychosis; for instance, in the case of a subject who contemplates suicide, there may be an over-stimulation on the stage which may cause him to mobilize all his mental resources towards an act of self-destruction.

PSYCHOLOGICAL CORPORATION,

THE.—This is a business organization for the advancement of psychology and the promotion of its useful applications. Its main office is located in New York City, where a staff of psychologists and assistants is maintained. As of 1944, over one hundred persons were employed in this office, and some two hundred psychologists throughout the country cooperated as research associates in the various services rendered by the corporation.

SERVICES

The corporation's staff has developed and now operates the following services, each handled by a semi-autonomous division:

Marketing and Social Research Division. Conducts consumer surveys in cooperation with psychologists throughout the country. Deals with problems in the fields of selling, advertising and public opinion. Makes continuous studies of trends in buying behavior and public opinion based on ten thousand interviews every three months, known as The Psychological Barometers, established in 1932-33.

Industrial Division. Renders consulting services on employee selection and upgrading procedures and development of supervisory personnel. Installs employment tests and trains company interviewers and test administrators. Interviews, tests and renders comprehensive reports to companies on men being considered

for sales and executive positions, or for other specialized lines of work.

Test Division. Serves as a publishing, sales, advisory and research agency for psychological tests and materials. Issues annual catalog of representative tests, and bulletins from time to time describing new developments. Conducts research for construction and standardization of new tests and the improvement of present forms.

Testing Service Division for Schools of Nursing. Tests applicants for admission to schools of nursing throughout the country, with the cooperation of local psychologists and qualified test administrators. Conducts continuous research on tests and student selection procedures.

The Psychological Service Center—Clinical Division. Provides aptitude testing and practical psychological counsel on educational, vocational and personal problems of adults and children. Conducts testing programs, studies of individual pupils and other psychological work for schools and institutions.

HISTORY

The corporation was organized in 1921 by Dr. James McKeen Cattell and a group of forward-looking psychologists. It was established as a business corporation, but not for the individual profit of the incorporators, stockholders, or directors, beyond reasonable compensation for services rendered. The idea of the founders was that the economic value of psychological work could be capitalized for the benefit of the science, and hence the corporation is committed to utilize a share of its profits to promote the advancement of psychology by research, the more effective organization of psychological work, and the diffusion of knowledge concerning psychology. For the first ten years of its existence, the financial results of its operations were not very promising, but since 1930, when steps were taken to organize and build up a competent staff, its earnings have steadily improved, and in 1944 its gross income from the operation of its various services was over \$700,000. About 20 per cent of this income, however, was derived from the operation of a temporary War Research Division executing contracts with the U. S. Federal Government's Office of Scientific Research and Development.

The board of directors of the corporation, twenty in number, has consistently comprised

recognized leaders in psychology, and the presidents of the corporation have been, successively, James McKeen Cattell, Walter V. Bingham, R. S. Woodworth, E. L. Thorndike, A. T. Poffenberger, Walter R. Miles and Paul S. Achilles.

The capital with which the corporation started business was \$10,000, raised by issuing one thousand shares of stock at no par value which were originally sold to psychologists at ten dollars per share. Dr. James McKeen Cattell maintained the controlling interest by retention of six hundred shares of stock, the balance being purchased in small lots by some two hundred other psychologists. In November, 1942, Dr. Cattell, by gift of his six hundred shares of stock, established the James McKeen Cattell Fund for scientific research and the dissemination of knowledge, with the object of obtaining results beneficial to the development of the science of psychology and to the advancement of the useful application of psychology. As of 1945, the trustees of this fund were A. T. Poffenberger, secretary-treasurer; Paul S. Achilles, managing trustee; Elsie Oschrein Bregman, Henry C. Link and Dean R. Brimhall, trustees.

RESEARCH

In addition to the advancement of psychology by the rendering of services of economic value, the corporation seeks to advance psychology by research. To a large extent, the services rendered to its clients are of a research nature, but it also conducts research to improve its own services and tests, or other materials which it offers for sale. Insofar as its funds permit, it seeks also to conduct, or to aid in the financing of, pure research. For several years it made grants in aid of research to graduate students and other psychologists, but subsequent to the establishment of the Cattell Fund, this practice was discontinued and a standing research committee of the board of directors now considers jointly with the staff such research as may be undertaken by the corporation itself, or by others with the aid of financing from the corporation.

PAUL S. ACHILLES,
Psychological Corporation

PSYCHONEUROSES.—Anyone who undertakes a systematic discussion of the psychoneuroses at the present time faces the

difficult problem of establishing the general nature of the reaction type which would be sufficiently broad to cover the vast number of heterogenous clinical manifestations that are usually placed in this group. This problem presented less difficulties when Dubois (1) first introduced the term. The group of disturbances which were discussed by him was comparatively small, and little was known about their internal complexity. But the progress that has been made since then, particularly in regard to the nature of these conditions and their etiology, has resulted in a gradually increasing complexity and a vast extension of the scope of this field. To the physician these discoveries have opened up new avenues of approach to clinical problems that have not hitherto been considered as belonging to the psychoneuroses. On the one hand it brought into this group a number of previously unrelated psychiatric conditions, in which more adequate methods of psychological analysis demonstrated mechanisms similar to those found in the psychoneuroses. On the other hand we gradually came to appreciate the fact that a large number of diseases which were hitherto considered as being of purely somatic origin could develop on the basis of personality problems and therefore both etiologically and therapeutically belonged to the field of the psychoneuroses. As a result the psychoneuroses have assumed a new and much broader role in the medical profession not only because of their wide prevalence but also because they have come to represent a link between the so-called psychic and somatic illnesses.

A further broadening of the scope of the psychoneuroses took place with the extension of the concept into fields outside of medicine. The contributions made by Freud and his followers in regard to the dynamics of psychoneurotic symptom formation have been found to be applicable to the studies of normal psychological phenomena, particularly to such aberrations from average behavior as crime and delinquency. Furthermore, attempts have even been made to apply these mechanisms to phenomena of group behavior and social pathological processes, thus introducing the somewhat questionable, even if popular, concepts of group neuroses.

All of this has resulted in two phenomena. On the one hand it has increased the impor-

tance of the concept of psychoneurosis to a pronounced extent and has made it imperative for anyone who attempts the study of medicine, psychology, or sociology to get a thorough grasp of the nature of these disturbances. On the other hand, with the increase of the variety of conditions included under this general term its limitation from other conditions has been rendered more obscure and it has loosened the degree of cohesion of the syndromes included within the group. Within the last few years, and particularly from developments during World War II, quite a few workers in the field have begun to doubt the value of continuing the term "psychoneurosis" as applicable to all the syndromes which it is supposed to include. Obviously, if we are going to discuss the field of psychoneurosis it is rather important to determine whether it still may be regarded as a practically useful term and, if so, to what particular conditions should it be applied.

This point is not of didactic importance alone. When Dubois first suggested the use of the term, he stressed the point that it should be applied to disturbances which are predominantly psychologically conditioned and which are, therefore, most likely to be helped by psychotherapy. As we follow the subsequent developments we find that the extension of its scope was primarily caused by the fact that psychotherapy could be successfully applied to a progressively increasing number of disturbances because of the discovery of their psychogenic etiology. From a practical point of view this is the most fundamental reason for maintaining the term and applying it to the syndromes which are included in it. In this sense it is actually of little importance whether all of these syndromes necessarily show similar clinical pictures, present similar prognoses, or are of similar degrees of severity. The question, therefore, that we wish to deal with here is whether there still exists a certain group of syndromes which, no matter what variations they may manifest in their clinical pictures and prognoses, show enough of similarity in their etiology and therapeutic indications as to be justifiably included under this one group.

Let us start out with a discussion of the type of disturbance that is diagnosed as psychoneurosis and see what the characteristic features of such a condition would be and to what syndromes it can be justifiably applied. For this

purpose we wish to present the following sample cases.

The first case is that of a 28-year-old married, white, American-born male who has recently been discharged from the armed forces with a diagnosis of psychoneurosis and had been referred from his place of employment with the following complaints: He has recurrent attacks of nausea, vomiting and diarrhea; occasionally develops pains and swelling of the hands and feet, and suffers from easy irritability and inability to concentrate on his work. He was born in a small Midwestern community. The family history shows high incidence of personality maladjustments, such as chronic "nervousness," restlessness, roving personality types, frequent unexplainable physical ailments, especially arthritic and genito-urinary disturbances, and mild depressions. The father and mother were poorly mated, and six months after the birth of the patient, who was the only child, they were divorced. The patient was adopted by his mother's married sister and did not know his true relationship to his real mother until after her death, when he was 23 years old. He lived with his adopted parents until the age of 13, at which time he had completed grammar school. At that time his adopted father died, presumably from a stomach ailment, and he went to live with another one of his mother's sisters, with whom he spent the next four years. Whereas the first home was a comparatively satisfactory one, the second one was characterized by lack of interest and affection, strict discipline, and economically poor status. During the latter period his life was made particularly unpleasant by two unmarried aunts whom he describes as hypercritical, domineering and frustrating every attempt on his part to undertake anything on his own initiative. From the beginning he seems to have been a very sensitive, introspective boy, given to self-observation and worry about his physical condition. The combination of domineering and protectiveness by his relatives resulted in a paradoxical attitude towards responsibility. On the one hand he revolted vigorously against discipline and criticism, particularly by women, and on the other hand he developed over-dependence upon others and an inability to make decisions on his own initiative. The one person in his family who showed him any affection and interest was his maternal grandmother, with whom he had periodic con-

tacts and to whom he was very much attached. He was of high average intelligence and graduated from college, majoring in journalism. His graduation came at about the time of the introduction of the Selective Service Act and he enlisted in the Army, being assigned to the Aviation Corps in a clerical capacity. Aside from the high degree of sensitivity and occasional hypochondriacal worries about his physical condition he had shown no symptoms prior to induction, with the exception of one incident. This came shortly before induction, one week after his mother's death. As was stated above, he did not know his true relationship to her and considered her as one of his aunts. She became ill with an obscure abdominal disease and at the same time his grandmother developed a severe case of arthritis. One week after his mother's death and directly after having been informed of the fact that she was his mother he developed swellings and pains in the joints of the hands and fingers. No organic reasons were found for this condition and he recovered from it spontaneously.

His experiences in the military service were quite varied. He joined as a private and later was promoted to the rank of corporal and was placed in charge of activities in which he had to direct a number of men under him. It was at this time too that he first met his future wife and her family. Unfortunately this family was quite clearly dominated by the girl's mother and her oldest sister, both of whom reminded him of his early contacts with his aunts, and he immediately developed an intense dislike to them. Apparently as a result of this, as well as the responsibilities of his work, he developed his first attack of gastro-intestinal trouble from which he recovered without any specific treatment and following that was sent overseas. His work overseas consisted of a number of dangerous missions in association with Intelligence activities. There, too, after having been promoted to the rank of sergeant and placed in charge of a detachment which had to do with serious liaison functions between various fighting units, he developed a second attack of gastro-intestinal disturbance. His performance in his duties was apparently quite satisfactory and because of his educational background and his abilities he was recommended for officer's training and was sent back to this country for that purpose. He received a course of training,

at the end of which three rather important occurrences took place in his life. Upon completion of his training he was commissioned a lieutenant in the Army and placed in charge of important Intelligence work. Shortly before that, he was called back to his home town because of the serious illness that his grandmother developed and which culminated in her death. At the same time he became engaged and subsequently married his present wife. His appointment to the rank of lieutenant took place after these two incidents and he had asked and received a three-day furlough to go to see his wife. On the way there he became ill on the train with an acute gastro-intestinal upset, collapsed, and had to be taken off and sent to a hospital. His condition was considered at first as being of organic nature, but a series of investigations failed to show any organic cause, and after a number of months, during which he had repeated attacks of the same condition, he was discharged from the Army with the diagnosis of gastric psychoneurosis.

His first attempt at rehabilitation was to apply for a position in which he could resume his journalistic work which was interrupted by the war. He was accepted on the staff of a large newspaper, but the work to which he was assigned consisted of cutting out clippings, a task which was far from being interesting. At the same time the wife's mother and sister were becoming progressively more difficult to get along with. Their constant criticisms and nagging led to severe quarrels and interfered with his attempts to adjust to an already unpleasant job. He finally decided to move to a small Midwestern town where he obtained a position which was more in keeping with his interests. The few months that he spent there were quite satisfactory and symptom-free. The wife, however, wanted to get back to her own home and finally succeeded in talking the patient into it. The return to the wife's home brought with it a renewal of the quarrels with his in-laws and to this was added the fact that he had to accept work which was neither interesting nor very highly remunerative. As a result the symptoms reappeared, he gradually became worse and was finally referred to our clinic. The treatment consisted in an analysis of his early experiences, the problems under which he was laboring, and the relationship between the development of his symptoms and these problems. Concom-

itant with that, the social setting was changed. He was aided in getting a new position and in moving out of his mother-in-law's home. At present the patient is symptom-free and is adjusting quite satisfactorily at his work.

The story of this patient and the development of his symptoms follows a fairly characteristic pattern. A special constitutional background and early environment have resulted in the development of a personality characterized by sensitivity and unusual interest in one's bodily functions. Added to this was a constellation of conditioning factors which made it difficult for him to adjust himself to the acceptance of adult responsibilities. Finally, a series of incidents in which there has been a re-enactment of the early conditioning influences facilitated the development of his symptoms. Furthermore, the symptom picture was characterized by somatic ailments for which no obvious organic cause could be found, as well as a general state of irritability and lack of ability to concentrate. In addition to these it was noted that his personality functions in general were not affected. He showed no involvement of his intellectual functions, there were no profound affect disturbances and no evidence of projections. This case serves as an example of a large number of similar conditions which, although they are encountered in civilian life, were particularly frequent in the military psychoneurotic casualties. They are sometimes referred to as psychosomatic disturbances, at other times as organ neuroses, but are conventionally placed into the group of the psychoneuroses. In the same group, however, we have been traditionally placing other forms of personality disturbances which superficially seem quite different from this one.

An example of one of these is the case of a man of 30 who, following a minor automobile collision, developed complete blindness without any signs of organic disturbance. His history showed a series of early experiences which conditioned unconscious fear of marital responsibilities. Sometime before the development of the symptom, he married and shortly thereafter the wife became pregnant. It was on his way to the hospital, where the wife had just been delivered of a baby, that the collision took place which resulted in blindness. An analysis of the case brought out the fact that the patient unconsciously used this symptom as a way out of meeting the responsibilities of marriage

which he dreaded because of his early experiences. The development of the condition is similar to that in the case described above, although the clinical picture is definitely different in that no actual organic pathology was found either as a cause or effect of the disturbance. We usually refer to this type of symptom complex as conversion hysteria and it is classified under the group of the psychoneuroses.

Finally, a third case showed a series of obsessive compulsive reactions in a girl of 24, who for years has been tormented by fears of contamination and handwashing compulsions. We found that the family history showed a number of cases of poorly adjusted personalities of the obsessive-compulsive types and she herself has always been of a rigid and ruminative nature. Early in life a series of sexual experiences took place, accompanied by feelings of guilt and fears of discovery and pregnancy. An attempt in early adolescence to establish heterosexual contacts resulted in an accentuation of the old fears and, given the personality type that was characteristic of her, she took flight into the fantasies of contamination and the resulting compulsive activities. This form of disturbance is usually designated as psychoasthenia, another subgroup of the psychoneuroses.

As we reach out further into the field of disturbances conventionally classified under this heading and consider such conditions as the chronic states of fatigue, acute anxiety syndromes, the diffusely complaintive hypochondriases, the phobias, convulsions, amnesias, and so on, we see how immense the variation in the clinical picture and in the severity of the disturbance can be. It is easy to see why serious doubts have been expressed as to the advisability of including all of these syndromes under a single group and if the clinical picture alone were considered it would be difficult to see of what practical use this would be. All of these syndromes, however, show some very distinct and fundamental similarities. Perhaps the most obvious, even if most superficial, of these is that to most people the term "psychoneurosis" denotes symptoms for which no obvious reasons can be discerned. Whether these are headaches or gastro-intestinal disturbances, phobias or amnesia, one fails to see on the surface any organic or conscious psychological reasons why the person should have such symptoms. Another feature that they have in common is that the

symptoms seem to serve some purpose. In other words, they serve as a sort of social barter used by the person to obtain a solution to a problem which he otherwise cannot solve. If we go more deeply into the nature and manner of development of these disturbances we find further that in most of these cases we are dealing with individuals who, even before the onset of the symptoms, have shown certain characteristic personality traits which they may have inherited or acquired very early in life, but in either case they have been consistently peculiar to this person throughout his life. More important than this, however, and actually to be considered as the deciding factor in the development of the symptoms, is a series of conditioning experiences occurring during the formative years of life, which on the one hand lead towards the establishment of a conflict in the process of adjustment to important instinctive function and, on the other, set a pattern for the symptom complex which the patient uses as a substitute solution of the problem. Finally, we see that the onset of the symptoms occurs in reaction to a situation, the stress factors of which are specifically related to the patient's individual vulnerability. It is true that as we analyze different cases we find wide variations in all three of the above-mentioned causative factors. In all of them, however, the one feature that stands out as most characteristic is the fact that the symptoms develop in relationship to socio-psychological entanglements, the correction of which removes the need for symptom formation. It is because of this fundamental aspect of the psychoneuroses that the development of psychotherapy is so intimately associated with the history of these disturbances. The appreciation of this relationship was basic to the original concept of Dubois, it forms the central core of the analytic approach to the neuroses, and finally it is the main practical reason for the development of the field of psychosomatics. The guiding principle in all of these is the idea that since these symptoms are of psychological origin they can be treated psychotherapeutically.

From a practical point of view it is, therefore, important first of all to gain an insight into the manner of development of these disturbances and thus secure a foundation for therapeutic procedures. Then we must learn something about the various types of clinical manifestations we are likely to encounter in this field, and

finally, we will have to acquaint ourselves with the methods of differentiating the psychoneuroses from other types of personality disturbances. It is proposed to take up these three problems in the following paragraphs.

ETIOLOGY

It is obvious that within the limits of the present contribution the vast amount of data that have been accumulated, particularly within recent years, in regard to the manner of development of the psychoneuroses, cannot be exhaustively treated and we must refer the reader to more detailed exposition of the subject for further information. From what has been said above we can see that three factors seem to combine in producing these syndromes: the constitutional, the developmental, and the situational, although in different cases one or another of these factors may have predominance.

Constitutional Factors. Perhaps the least well defined of the three are the constitutional factors. It is obvious that personality characteristics do not lend themselves easily to investigations along genetic lines. It is true that in most of these cases we find that the family history usually shows a higher than average incidence of personality characteristics frequently closely related to the types manifested in the patients themselves and which may render them predisposed towards the development of psychoneurosis. Also, it can be noted that the well-known constitutional types, as for instance, those which have been described by Kretschmer and more recently by Sheldon (2), and which are presumed to have an hereditary basis, are frequently encountered in this group. Thus we find the introverted, hair-splitting, scrupulous, pedantic personality type, more likely than not of the leptosome physical make-up as the soil on which the obsessive-compulsive syndrome will develop. Similarly, the histrionic, sentimentally demonstrative extraverted person is frequently the one who develops hysteria. Finally, the various psychosomatic disturbances also seem to develop most frequently in certain types of personality make-up. All of which would suggest an hereditary background at least as a determinant of vulnerability. At the same time we find in the histories of these patients certain personality characteristics which facilitate the development of the disturbance and

which have been manifest before the onset. Whether this is entirely on the basis of genetic factors or whether it may develop because of environmental influence during the most formative years of life remains a question. We may regard all of these factors as constitutional, if we mean by constitution a combination of factors that have been inherited and those which have been acquired so early in life that they have become part of the personality and cannot be manipulated by the environment. Furthermore, we can say that although it is not absolutely essential that such a set of constitutional factors must be present in every case of psychoneurosis, nevertheless the development of a psychoneurosis is facilitated by the presence of such a personality.

Developmental Factors. In the histories of the three patients described in the introduction it was noted that certain experiences in the early years of the patients' lives had exerted an important effect on their subsequent behavior and particularly on the development of the symptoms. It is generally agreed that this is true of symptom formation in psychoneuroses as a group and since such experiences take place during the growth of the person they can be designated as developmental factors. They may affect personality functions in either one of two ways. In the first place the child may take on certain general characteristics that are peculiar to the persons in his immediate environment. This may be accomplished by purposeful imitation, by unconscious identification, through conditioning and other processes of this type. A certain number of these characteristics may become so firmly fixed as to be rendered permanent personality traits. In view of what was said in the preceding discussion of constitutional factors, it is obvious that such personality traits cannot be easily, if at all, differentiated from hereditary characteristics, nor is it particularly important to do so. We must, however, appreciate that their influence is primarily of a predisposing nature, in that they may make the individual susceptible or vulnerable and thus provide suitable soil for the development of psychoneuroses. It is obvious that those characteristics which develop earliest will tend to be most firmly fixed and are, therefore, more closely related to the constitutional factors, whereas the ones that are acquired at a later stage are likely to be less permanent, more

easily manipulated by re-education and therefore more amenable to treatment. These latter could be regarded as developmental in nature. Whichever of the two phases we are dealing with, the important thing is that they represent primarily potentialities and not specific etiological factors.

As contrasted with these we find in the cases presented above, as well as in most patients suffering from psychoneuroses, certain experiences occurring during the development of the person which may affect them in such a way as to lay the foundation of the future psychoneurotic disturbance and even determine the type of symptom complex which develops in reaction to stress situations. These experiences must be regarded as specific in nature and they are the ones that are usually dealt with in the process of psychotherapy. Generally speaking, it may be said that traumatic experiences of this second type occur most frequently in relationship to two important developmental processes, namely: (1) the organization of the instinctive life, and (2) the establishment of conditioned reflexes.

(1) The first of these refers to the process of integration whereby the vital biological needs, such as self-preservation and sex, are organized during the growth of the individual in relationship to each other, to the outside world, and to the developmental changes that take place in both. There are three conditions which make it particularly likely that traumatic experiences of considerable importance would occur in this process. In the first place, it is obvious that since these biological needs are expressive of different types of function they will also differ in their objectives. Whenever these objectives are actually opposed to one another we may find the person being impelled in opposite directions at the same time. A conflict will thus occur and if the two forces do not succeed in neutralizing each other completely, the result will be a gratification of one instinctive need and repression of the other. But repression naturally leaves a potential need for gratification and, therefore, a continuing search for an outlet, until such gratification has in one way or another been attained. Secondly, it must be realized that even if the objectives of all of these instinctive needs coincide they may be opposed to the interests of the outside world and thus lead to a conflict with it. This situation is

further complicated by the fact that the need of adjusting to the outside world may be conditioned by what we expect in return in terms of security, approval, recognition, and so on. A conflict may thus be established between the internal instinctive needs and the dictates of organized environment, and here, too, the result will be repression with consequent search for an outlet. Finally we must remember that the individual, during his development, undergoes a process of maturation during which the methods of reaching the objectives of the instinctive needs, or the objectives themselves, may change. This is especially well demonstrated in the case of the sexual drive where throughout the formative years of life and until the adult heterosexual stage is reached, the person shifts successively from one method of gratification to another. During any one of these stages the pattern of gratification becomes more or less firmly entrenched, and when, because of physiological and socio-psychological development, the old method has to be replaced by a new one, a conflict will ensue in the process of emancipation from immature patterns of behavior. The result here too will be repression and subsequent search for outlets.

We see, therefore, that the process of organization of the biological needs in all of its phases is likely to give rise to repression and search for outlets. In the average person these outlets are provided by incorporations of early needs into new methods of gratification, substitutions, and compensations which do not interfere too seriously with adjustment. Where for one reason or another this is not accomplished, either because the repression is too strong or too permanent, or another outlet is not available, then pathological forms of gratification of such needs must be developed and these manifest themselves as symptoms of personality disturbances. These symptoms may be the direct outcome of such repressions in terms of tensions, anxieties, or withdrawal from contacts with the outside world. If the person has not succeeded in emancipating himself from earlier levels of adjustment, symptoms such as feelings of guilt and fear of punishment may result. Finally, they may lead to the development of pathological substitutions or compensations in the form of conversions, compulsive phenomena, etc.

(2) The investigations that have been re-

ported in the field of conditioned reflexes, both in normal behaviors and in the production of experimental neuroses, have demonstrated the fact that psychoneurotic symptoms may also develop on the basis of either accidental or purposeful combinations of indifferent stimuli with those that are specific to biological functions. In the first place, it has been shown that if certain primary biological activities are accompanied by experiences which are not specifically related to them, these combinations may lead to the establishment of conditioned patterns of behavior. Thus it is easy to see how the ingestion of certain foods may become combined with feelings of fear, disgust, or even symptoms of physical distress. Similarly sexual experiences may be combined with feelings of guilt, fear of punishment and general anxiety. In the second place, since the organization of instinctive needs, particularly in their relationship to social behavior, is very largely dependent upon conditioning, situations may develop in which the performance of these functions may become too complicated and difficult of achievement and thus lead to states of anxiety and tension. Actually most of the experimental neuroses produced in animals develop on this basis. Investigations of patients with psychoneurotic disturbances show that this mechanism frequently forms the basis of psychoneuroses in man also.

What was said above in regard to these developmental factors obviously represents only a very sketchy and incomplete account. A great many investigations have been undertaken and reported in this field in relationship to the two processes mentioned above as well as other important phases of development. For further information on this subject the reader is referred to the literature on psychoanalysis (3), conditioned reflexes (4), experimental neuroses (5), and other contributions to dynamic psychology and psychopathology.

Situational Factors. The process of adjustment to any new setting depends upon two sets of determinants: the person as he is at the time, and the situation which he has to meet. The first of these is determined by the person's constitutional characteristics as they were modified by his developmental experiences. The second consists of the situation itself and whatever stress factors may be included in it. The extent to which these latter determine behavior

in general, and psychoneurotic behavior in particular, is what we would designate as situational factors. It is obvious that the number and variety of all possible situational determinants is in fact infinite in its scope. For systematic purposes, however, we may consider these as consisting of the following categories:

1. *Social Factors.* The human being is a social organism depending upon society not only for protection, approval, and recognition that he gets from it, but also for what he can, and desires to, give to society. In a dynamic system as society is, we must naturally expect a good deal of fluidity, with resulting changes that demand a continuous change in adjustment. Under ordinary circumstances these changes, however, are not great enough to place too much stress on the individual. But where a more drastic change takes place, the individual is called upon to undertake more radical changes within himself, and if he has been rendered vulnerable either by constitution or by traumatic experiences, a failure in adjustment may occur. Whether these changes are of a general nature as are encountered in such social upheavals as war, revolution, mass panics, etc., or whether they are more localized either to the group in which the individual lives or even to his own narrow family circle, the result will be the same, in that, depending upon the intensity of the situational stress and the vulnerability of the person, a specific break in adjustment may take place.

2. *Economic Factors.* In a society where status and security are mainly dependent upon the economic setting of the individual himself or the group in which he lives, it is quite understandable that drastic economic changes may precipitate personality maladjustment. Country-wide depressions and economic class struggles, or personal difficulties with loss of savings or of a job may, depending upon the personality of the individual, lead to psychoneurotic symptom formations.

3. *Personal Factors.* Throughout the life of each person, changes in his own personal organization occur by virtue of the fact that he is a dynamic, biological system. The infant, if he lives, is bound to develop into the child, the child into the adolescent. The adolescent matures and has to take on new responsibilities. The mature person goes through a period of productive life and then involution sets in with

the subsequent development of senility. Although the process of development is a continuous one, nevertheless certain periods of life are characterized by especially radical changes. Puberty, marriage, the menopause in women and, perhaps, climacterium in men, all occur more or less abruptly. Each one of these points may be regarded as a critical stage at which adjustment will be rendered particularly difficult. Here again, given a certain type of constitution and specific developmental experiences, the ability to adjust may be strained to a breaking point, especially if the person is not prepared to make the transition.

4. *Organic Factors.* Finally we must take into account the importance of organic factors as possible situational determinants of maladjustment. Acute febrile diseases or chronic debilitating ones, injuries, especially such that are disfiguring and crippling, may be difficult to adjust to, particularly if the person has been made vulnerable to such stress by earlier factors. Toxic agents, exhaustion, deficiencies in nutrition also are known to act as stress agents which may precipitate the development of personality disturbances. It is true that in the psychoneuroses we do not regard organic etiologies as being of primary importance, but they can and do frequently act as contributory factors in the sense of precipitating causes. Here we might also mention the fact that organic factors can act in an indirect manner. By this we mean that even if the person has been able to adjust himself to the acute effects of, let us say, infantile paralysis and come through with a normal adjustment to these, the resultant sequelae such as crippling and atrophies, particularly if they happen early in life, may in themselves create constant sources of feelings of inferiority and inadequacy and thus lead to the development of compensatory mechanisms.

CLINICAL MANIFESTATIONS (6)

In the introduction it was emphasized that at the present time the number and variety of clinical syndromes that are placed in the group of the psychoneuroses is so immense that it has actually become questionable whether they can all be regarded as belonging to one nosological entity. In clinical practice we find that these countless cases are at such variance with one another that each one represents a new phenomenon in itself. Nevertheless in an arbitrary

way we can divide the whole field into several broadly conceived groups of symptom complexes and these are as follows:

1. *Conversion Symptoms.* The second case that was quoted above of the man who developed blindness in reaction to a conflict situation represents a typical example of what is known as conversion symptom. We mean by it that the individual develops a symptom, usually somatic, which does not have, as far as anybody can see, etiologically relevant organic pathology. Furthermore, this symptom seems to help the individual to deal with a dilemma which he cannot otherwise meet. Reactions of this type are known as conversions. The variety of possible conversion symptoms is, of course, very great. Perhaps no system of the organisms is immune to the possibility of conversion symptoms. Most frequently we encounter the following types of symptoms: (a) *Motor.* Here we find paralyses of voluntary muscles such as the arms or legs, interference with the function of the bladder or gastro-intestinal tract, vomiting, paralysis of the vocal cords, tremors, etc. (b) *Sensory.* Here we find anesthetics or analgesias, pain or other unpleasant sensations and disturbances of the organs of special sense such as blindness, deafness, etc. (c) We may also find in this group mental symptoms that frequently are known to develop in organic disease of the nervous system such as amnesia and delirium. When conversion symptoms are the main features of the psychoneurosis the condition is classified under the syndrome of *Hysteria*.

2. *Anankastic Reactions* (7). This term was proposed by Schneider to designate symptoms which are characterized by compulsive features. They may occur in the form of thoughts, feelings, or acts, the pathological nature of which the patient realizes but is compelled to experience them and react to them even though he sees no good reason for doing so. They too, of course, develop in relationship to psychological mechanisms, the nature of which was discussed in the section on etiology. Three types of such symptoms may be described as follows: (a) *Obsessions.* These are anankastic thoughts that continually intrude themselves upon the person against his own will so to speak. The mother who is continually obsessed with the idea that she may kill her child; the religious person who is obsessed with thoughts of blasphemy and sacrilege; thoughts of suicide or self-mutila-

tion, and others like them may be encountered. In all of these the person may feel reasonably certain that he is not going to follow out the action itself but is continually tormented by these thoughts and is incapacitated in his other activities because of them. (b) *Phobias.* These may be defined as unwarranted fears: claustrophobia, agoraphobia, nyctophobia, astrophobia, aichmophobia, are examples of this type of symptom. The patient may realize, logically, that there is no basis for his fears but he is unable to force himself into the situation in which the symptom is centered. In that sense they may become completely incapacitated in their work and general adjustment. (c) *Compulsive Acts.* These are various ceremonial, ritual, or habitual activities which the person feels forced to undertake even though he realizes the lack of any good reason for doing so. Compulsive handwashing, the compulsion to touch things or to count cracks in the sidewalk are examples of this type of reaction. In some cases, for example, peculiar movements, tics, uttering of meaningless sounds, the symptoms do not have any obvious meaning in themselves but are symbols of deeper-lying psychological urges which in turn depend upon earlier traumatic experiences. These, too, may increase to such an intensity that they interfere with the activities of the individual to the point of real maladjustment. Psychoneuroses which are characterized predominantly by anankastic symptoms are classified as psychasthenias.

Both hysteria and psychasthenia are furthermore characterized by certain general attitudes. In the first, we usually find the dramatic, martyr-like exhibitionism with which the patient parades his symptoms for the benefit of the observer. In the second, we find a great deal of reticence, introversion and, frequently, depression. This difference in attitude is closely related to the types of personality in which these disturbances are most likely to develop and which were discussed under the section on constitutional factors.

Faulty Control of Emergency Measures. (8) It is a well known fact that human beings show characteristic psychobiological responses to emergency stress situations. In the case of vital danger, for instance, the subjective feeling of anxiety is accompanied by definite physiological changes such as rapid pulse, increased blood pressure, changes in blood sugar, etc. Simi-

larly we find that when muscular exertion reaches a degree which is above the limits of average endurance for a given individual the phenomenon of fatigue is produced which manifests itself in both the subjective feeling and related biochemical changes. From a practical point of view it is important to emphasize the fact that both of these serve useful purposes with regard to the stress situation. The phenomenon of anxiety facilitates quick muscle activity resulting in either fight or flight, fatigue leads to cessation of further exertion. Because of this we may regard them as emergency measures. Psychologically we can also recognize other forms of emergency measures such as feelings of inferiority in facing a task which is beyond one's capacities, feelings of guilt in facing a situation that may lead to clash with the group and others. It is obvious that under normal circumstances where these responses occur in the presence of actual emergencies, they are not only to be regarded as normal but as useful reactions. In pathological conditions, however, we may find emergency measures of this type developing in the absence of actual emergencies but on the basis of mechanisms peculiar to the psychoneuroses. The most characteristic examples of this type of reaction are found in the anxiety states and neurasthenia.

Anxiety States. Clinically these are characterized by attacks of unexplained but intense anxiety which can be best described as similar to the fear reaction that an average person experiences when facing vital danger, but differs from it in that no such danger is present and in most cases not even imagined to be present. The concomitant symptoms are also similar to those found in normal fear reactions; chills, a sense of pressure in the head and precordial regions, cold perspiration, palpitation of the heart, and frequently increased pressure. Added to these, we may find such symptoms as alternating constipation and diarrhea, dizziness and even vertigo. At times we find these reactions occurring in relationship to anticipation of possible danger or following exposure to dangerous experiences, but where no actual danger exists. In most cases, however, such states develop without any reference to actual danger but where unconscious conflicts dependent upon past experiences may be brought to the surface by certain situational factors which in themselves need not be indicative of danger. In most

cases the condition manifests itself in acute attacks with intervening periods during which the person is quite well. In other cases it may gradually develop into a state of chronic anxiety, lasting for a long period of time without any intermissions.

Neurasthenia. Clinically this condition is characterized by feelings of physical and mental inadequacy, complaints of fatigue without adequate exertion, parasthesias, and a sense of general weakness. With this there may be an accompanying increase of irritability, lack of ability to concentrate, sexual impotence and, at times, a vague sense of anxiety. These conditions are usually of a chronic nature and in contradistinction to the anxiety neuroses occur most frequently in people who have always been known as chronically nervous with morbid introspection.

Psychosomatic Disturbances. The present day concept of the nature and manner of development of these disturbances is primarily based upon two important observations. In the first place, we have the investigations of Cannon (9) and his followers which showed that strong emotional experiences can produce changes in physiological functions. Such effects could be especially well demonstrated in the cardiovascular system, the digestive organs, and the glands of internal secretion. In the second place, recent clinical observations have shown that certain somatic disturbances are subject to influence by changes in the emotional state of patients. Increased emotional stress leads to exacerbation, whereas decrease of the stress produces amelioration sometimes to the extent of complete disappearance of the symptoms. As a result of this work attempts have been made to investigate a number of these syndromes in order to further our knowledge of the underlying psychogenic mechanisms and to develop appropriate psychotherapeutic methods of treatment. Although the whole concept is of comparatively recent development, it has already spread in its scope to include a very large number of conditions which have hitherto been considered as of primarily somatic origin. Some systems of the body apparently are more frequently affected in this way than others. Amongst the most important are the following:

A. Gastro-Intestinal Disturbances. (10) A good example of this type of disturbance is afforded by the first case described in the in-

roduction. The patient experienced severe gastro-intestinal upsets in response to emotional stress situations. In studying this case we found that the early experiences of this individual have created a conflict situation in his adjustment to adult functions and responsibilities. At the same time it was noted that in his family there were instances of similar reactions, a fact which may be regarded as indicating either constitutional predisposition or the establishment of patterns of reaction on the basis of identification. The important fact in the case was that the discovery of the mechanisms whereby these disturbances were produced and the removal of noxious elements in the situation have led to a disappearance of the symptoms. Different types of gastro-intestinal symptoms, such as spastic colitis, mucous or even ulcerative colitis, syndromes akin to those of peptic ulcer, and others have been reported as developing on an essentially similar basis. It is interesting to note that although instances of this type are frequently found in civilian practice, they were observed in particularly great numbers amongst the members of the armed forces.

B. *Cardio-Vascular Diseases.* (11) The occurrence of hypertension in young people without signs of underlying organic etiology and the fact that emotional stimuli seem to have such a pronounced effect upon the cardio-vascular system has led to an investigation of the role played by psychological mechanisms in disturbances of this system. The results reported by a number of observers indicate that factors of this type are etiologically important. In addition it has been found that in cases of organically conditioned cardio-vascular changes, exaggerations of the symptoms can be produced by emotional stress and, therefore, must be taken into account in their treatment.

C. *The Endocrine System.* (12) A good deal of evidence is available of the close relationship that exists between various endocrine disturbances and personality problems. Even in normal people one finds close relationships of this type as is evidenced by the frequent occurrence of disturbances in menstruation, sexual activity, and adrenal functions on the basis of emotional stress situations. Reports are also available in the literature of the important role that is played by emotional factors in the development and course of diabetes as well as in disturbances of thyroid function. The occurrence of im-

tence and frigidity in some of the other types of psychoneuroses points in the same direction. On the whole it is obvious that endocrine disturbances can certainly be aggravated and perhaps even produced by mechanisms which were described in the section on the etiology of the psychoneuroses.

A number of other organ systems are similarly influenced. In the first case quoted in the introduction we found that the gastro-intestinal systems sometimes alternated with swelling and pain of the joints, which were also apparently dependent upon emotional factors. Although investigations of the various types of arthritis have not resulted in as clear cut demonstrations of this relationship, it seems quite probable that here too similar mechanisms may be at work. (13) Allergic reactions, (14) such as hayfever, migraine, asthma or skin disturbances have also been shown to be closely associated with and perhaps largely dependent upon psychological mechanisms. This was also demonstrated in cases of atopic dermatitis. (15)

The whole field of psychosomatic medicine is in the early stages of development and is at present being systematically investigated. For further information on this subject the reader is referred to several excellent reviews of the available literature. (16)

The above described syndromes represent the majority of clear cut subgroups of the psychoneuroses. In actual practice one of course finds numerous instances which are not clearly differentiable. Many of the cases do not seem to be representative of any one single group but of combinations of several. Thus we find anxiety states with marked psychosomatic symptoms; hysterical conversion syndromes combined with compulsive phenomena and so on. In the clinical nomenclature these are usually placed under the heading of Mixed Psychoneurosis and it must be said that this group in itself takes in a large proportion of the cases of psychoneurosis seen in actual practice. Mention must also be made of a syndrome frequently designated as hypochondriasis. It is characterized by vague pains and aches unsystematically scattered throughout the body and accompanied by states of irritability, fatigability, and inability to concentrate. Actually it seems to consist of a combination of hysterical and neurasthenic syndromes.

Delimitation of the Concept. A detailed dis-

cussion of differential diagnosis is beyond the scope of the present contribution, since it does not deal primarily with practical clinical considerations. It seems advisable, however, to point out, in a general way, the main features used in delineating this group from other related disturbances since it would help to emphasize the characteristics peculiar to the psychoneuroses. With regard to other types of personality disturbances the most important conditions which should be considered in this connection are the Psychoses, particularly the so-called functional types. Etiologically these are closely allied to the psychoneuroses, although in the latter the dependence of the disturbance upon the psychological mechanisms described above is more frequently established and more clearly understood. The most important differentiating features are found in the clinical pictures. Such symptoms as clear cut conversions, obsessions, phobias, or psychosomatic disturbances are definitely indicative of psychoneurotic rather than psychotic reaction types. As opposed to these we find in the psychoses certain distinctive symptom complexes that do not occur in psychoneurosis. Distinct projections and distortions of external reality such as paranoid delusions or hallucinations do not occur in psychoneurosis. Similarly, primary mood disturbances, as we find them in the manic depressive group, intellectual deterioration as we find them in the organic psychoses, and disturbances of the affect and the thought processes as we find them in schizophrenias, should militate against the diagnosis of psychoneurosis. In a general way, then, we can say that the psychoneurotic disturbance does not affect the personality to as pronounced an extent either in depth or in scope as do the psychoses. Finally, the psychoneurotic as a rule has good insight into the fact that he is sick; and his adjustment, beyond his particular symptom complex, remains more or less unaffected.

Difficulties frequently arise in differentiating the psychoneuroses, particularly the conversion types, from purely somatic diseases. Here we must rely on the one hand on laboratory and physical examinations which, in the somatic conditions, would indicate the presence of an etiologically relevant organic disease. At the same time it must be remembered that the characteristics of a conversion symptom are determined not by anatomic relationships but

on the basis of the idea of the part of the body involved. Thus it is that glove and stocking anesthetics are practically unknown to occur on an organic basis, but are logically the types of anesthesia that would occur in conversions. Double vision, persisting when one eye is closed, precordial pain that is diffusely distributed over the general region of the heart and is not distributed down the left arm, all illustrate the same principle.

Another group of conditions from which the psychoneuroses must be differentiated are the predominantly constitutional personality disturbances, particularly those classified as psychopathies. Here we rely primarily upon the admittedly vague criterion of hereditary etiology. Taking into consideration the fact that constitutional characteristics cannot be definitely differentiated from those acquired early in life, we will have to admit that in a large number of psychopaths, psychoneurotic mechanisms may be at work and vice versa, that so-called constitutional characteristics may be largely responsible for the development of some psychoneuroses. The history of the occurrence of similar patterns of behavior in the ancestry and a fairly consistent failure of adjustment throughout the life of the individual, without any clear cut onset of new symptoms, would be a deciding factor in favor of the diagnosis of psychopathy.

Finally a word must be said about the difficult problem of differentiating psychoneurotic syndromes from malingering. It must be stressed that the latter term should be used only to designate consciously motivated, deliberate and sustained simulation of symptoms in order to secure a desired end. It is true that psychoneurotic symptoms too serve definite purposes, but this is not consciously appreciated by the patient and the goal attained need not be actually desired by the adult person. As a result, we find that a psychoneurotic symptom is frequently not related at all to the situation in which the patient finds himself at the time but is relevant to a much earlier setting. Furthermore, the psychoneurotic, unlike the malingerer, not only does not object to examinations but actually asks for frequent and thorough investigations of his symptoms. Finally, it must be emphasized that the symptoms of the psychoneurotic are just as characteristic of this group and as difficult to simulate as the symptoms of

organic diseases. As long as we keep in mind the fact that psychoneurotic symptoms are specific manifestations of unconscious psychological mechanisms, they will not present any greater difficulties in differentiation from malingering than the symptoms of any other disturbances.

PSYCHOPATHIC BEHAVIOR: INDIVIDUAL AND GROUP.—It is only within the past few years, aided by the insights granted by dynamic depth psychology, that the phenomenon of psychopathic behavior has been somewhat clarified. Until recently, this variety of behavior—disruptive, episodic, and aberrative—was regarded as either a natural consequence of a perverse biology, or as wilful and calculated waywardness. The several psychological schools reflected the first view; while the philosophico-religious championed the latter. Because the mechanisms of the condition were veiled, due to an inadequate investigative approach, it was possible only to describe the varieties of psychopathy as these were encountered in the clinic or in life itself. There resulted, then, from the prisons and police courts, from the clinician's office and the minister's study, a catalogue of types. The word "psychopathic" became a repository, a miscellany, wherein was fitted, with Kraepelinian thoroughness, every instance of communally unsanctioned behavior, every example of conduct that did not accord with the usual or expected, and which could not be conveniently fitted under another rubric.

Perhaps the chief difficulty to the comprehension of psychopathic behavior, the main reason why it was for so long in service as a psychological waste-basket, was that it was

possibly the only aberrative condition which lacked a theme. In this, it remained unique among the disorders and diseases called mental. It was, so to speak, unintegrated, disorganized. In its afflicted, one could not point to a systematization of thought, as in paranoia, or emotive impairment, as in the schizophrenias, or mood alterations, as in the mania-depressions. One had only an illogical and almost implausible chaos of action and affect which mimicked every other pattern but yet managed to maintain an elusive distinctness.

This confusion had two important consequences. Not only were psychopaths unrecognized and misunderstood, but they could not be treated. The therapist was desperate in his search for treatment modes, and when these could not be found, he abandoned the whole thing with a convenient pronouncement that, for one reason or another, the condition was untreatable. In places where psychopaths were kept, they were exposed to the empiricisms of bright but unfounded notions, or subjected to "shotgun" methods that subsisted on trial-and-error, salted with prayer and exhortation. Equally significant was the result that science could only founder when it came to understanding and explaining the behavior of groups such as crowds or mobs in their psychopathic manifestations. And this, it may be, was a hiatus in knowledge more serious than any other, because of its social and political pertinence. Thus until psychopathy as an individual behavior variant was understood, and then this understanding applied to group psychology, such phenomena as the lynch mob, the anti-Semitic group, the Fascist party, and allied groupings, were beyond the ken of the psychological sciences.

The secret of psychopathic behavior has been uncovered by dynamic, depth psychology. The patient application of analytic principles has opened new avenues of approach to the disorder called *psychopathic personality*, and has, as a result, extended to both individual and group manifestations of psychopathy.

II. PSYCHOPATHIC PERSONALITY

In the light of modern research, it would appear that psychopathic personality is a valid clinical entity which circumscribes an individual who is both physiologically and psychologically unlike his fellows. It is a disorder, like all

others, with an inception, a course, and a prognosis. It is not (or should not be) used to describe anything which cannot otherwise be categorized. Perhaps it is best delineated in terms of predisposition and precipitation.

It would seem that the psychopath, as we meet him in prisons, hospitals, or in the ranks of certain political parties, possesses a physiology, a physico-chemical organization, somewhat different from other individuals. From Lombroso to Hooten, from every prison guard and hospital ward attendant comes testimony to the apparent if often unmeasurable departure from the normative in mere appearance alone of the psychopath. He is lithier, more agile, trim, "cat-like" in his movements, inclined to appear more youthful. And in support of these hypotheses, there is corroboration from the laboratory. When his great bodily systems are tapped and measured, it appears that the patterns into which they fall under varying conditions are, in truth, recognizably and significantly different from those obtained with other individuals. From electroencephalography comes strong evidence of differential brain-wave patterning. That these appear too in the behavior disorder of childhood—which in every case precedes the full-flowering of adolescent and adult psychopathy—argues pointedly for the view that there is, to the disorder, a complex predisposing physiology.

However, despite the possession in any one individual of a predisposing physiology, the psychopathic behavior state does not ever become manifest unless it is touched off, precipitated, by certain crucial, traumatic, dramatic, and decisive events of early life. Exactly what these events might be is not quite so important as the effects they have, and we will not here be concerned with their enumeration. Suffice to record that they eventuate in a restructuring of the personality in such a manner that its components are altered. The developmental course is arrested before an adequate resolution of the oedipus situation has been achieved. The fixations of the preoedipal period are maintained throughout life and lead subsequently to the initiation of actional courses aimed at achieving or satisfying them. Since society is introjected through the father, and this is unsuccessful in view of the preoedipal terminus to development, the superego remains stunted, authority hereinafter rejected, sexuality chaotic,

morality deficient, guilt from residual fancies of incest and parricide always overwhelming, and fear of castration a permanent dread.

The concatenation of crucial events which conspires to produce the psychopath when it exerts upon a predisposed physiology makes the psychopath what he is—"the grown up child of the pleasure principle." He is essentially infantile, demonstrating the impatience of infancy, its megalomania, its tantrum behavior, its divorcement from the requirements of reality, its narrowing of the "time-sense," even its psychosexual diffuseness. The aforementioned are the basal traits and tendencies of persons exhibiting the disorder, but for the explanation of the direction the symptoms take, and the explosive, spasmodic nature of their motor discharge, we have to look elsewhere.

Many observers have been struck by the fact that the psychopathic pattern is not always ongoing, as in other disordered or diseased states. They have remarked how alike it is, therefore, to the convulsive disorders, to the epilepsies, choreas, brain lesions, encephalitis. This fact has led to the formulation of the interesting proposal that the outburst itself—whether it be murder, an attack, a destructive act, or what not—is no more than a physiologically directed attempt to restore a disturbed homeostatic balance. It would seem that, in the individual psychopath, the organism is the seat of conflict between the infantile needs and the prohibitions of society; that such a conflict produces an accumulation of tension which threatens destruction; that a point is reached where a motor discharge is called for and vented; that this discharge restores the dynamic equilibrium in Cannon's sense. As to the direction of the discharge, it appears to follow closely the essential requirements of the particular personality, its wants, wishes, desires, and urgings which hark back to the first years of its life.

III. INDIVIDUAL PSYCHOPATHIC BEHAVIOR

It has been necessary to review the propositions basic to psychopathic personality for an understanding of instances of psychopathic manifestations in individuals who are not properly classified within this disorder. The typical psychopath presents a group of classical symptoms and signs which form a pattern or syndrome. But there are elements of psychopathy in all of us which, when properly evoked, lead

to examples of behavior paralleling and even, at times, surpassing what we expect and get from the bona-fide psychopath. What has often been attributed to uncontrollable temper, ungovernable impulse, or temporary insanity, is actually the appearance in the behavior field of a basal psychopathic trend which has remained, until that time, dormant. The mechanisms which underlie and govern such behavior outbursts are ancient to the performing organism; but that which evokes them, precipitates them, is a situational affair somehow reminiscent of early unfulfilled dramas. The response, on such occasions, is perennially infantile, and the mode of aggression invariably replete with transparent symbols attesting to the primitive motivation at the core of the act. Fully to adhere to the implications of what has just been said would, of course, mean to discard a segment of law which, be it noted, is premised upon an apposite fiction. Moreover, an acceptance of this view calls for a re-examination of our culture, particularly of the medium in which our children are immersed during the first years of life.

In contrast to the roseate fantasies which romantically color even our scientific regard of early life, infancy and childhood are *not* especially happy periods. The child is oriented pleasure-wise, but denying and punishing reality obtrudes at every turn. Existence, until the latency period at least, is a series of weanings, each difficult and filled with frustration. To bear them, numerous and devious defenses are called upon. But the original wants remain, even if their collective destiny is to fester in the hindmost recesses of the unconscious. Here they form a less tangible but no less real counterpart of the physician's "area of least resistance." When, in later life, the environment provides that which touches upon such focal points, or which penetrates the defenses of the ego, they find expression in act.

We come now to the chief distinction between the group of individuals who are viewed as psychopathic personalities, and the broad segment of the population—if not all the rest of us—that reacts psychopathically on occasion. It is simply that in the first the usual response is psychopathic because it is the expression of a personality which has not erected ego defenses against the intimate urgings of infancy, nor has it an adequate superego to utilize for repressive purposes; with the latter, the under-

lying psychopathy is evoked situationally when the defenses no longer avail to protect against the buried wishes. That this is so, is attested by the fact that much of the argument characteristically employed by defending lawyers or shocked intimates of an offender is to the effect that the act "was so out of keeping with his usual self." The act of the psychopath is, then, a part of his total personality and predictable as such. The act of the non-psychopath is unpredictable and part of only a segment of his personality.

The following case from the writer's files illustrates the foregoing proposals:

Our subject is a Negro, N., who at the moment of writing is serving a life sentence for murder. He is a very personable young man of 26, sturdily built, cheerful, and of average intelligence. The nature of his crime and the act itself is incomprehensible to him. He states, "I just can't believe it. I never did anything like that before."

N. was born on a plantation in a Southern state in 1918. His birth was normal but was followed by septicemia in his mother, who died of it seven months later. N.'s father, a field hand, felt himself incapable of raising the child, and on the invitation of his dead wife's parents, gave the infant to them for rearing. The maternal grandparents owned a small cottage on the edge of a neighboring town, and they were happy to share it with their only grandson. Here N. was raised, amid congenial surroundings and with what passed for affectionate care. The elderly couple were not demanding in their attitude toward the boy, but the age difference was so great that they did not understand him. While to all outward appearances he was a happy and healthy child, he was essentially lonely. It is interesting to note that he attempted to alleviate his condition by resort to a common fantasy in childhood, the imaginary playmate. He constructed for himself the pleasing fiction that he had a younger sister with whom he constantly played. From the age of three until he was seven, the phantasied playmate was included in all his plans, accompanied him everywhere, shared in all his little triumphs and disappointments. When he was sent to school, however, and began to mingle with other children, she was unceremoniously "forgotten," although he later seems to have dreamed of her.

Moreover, N. today thinks that to "her" is due the entire credit for whatever happiness his early years held. It is difficult for him to describe the atmosphere of the grandparental home. He tells that he was *not unhappy there* in the usual sense: they were kind to him; but he had an alienated "feeling," as if "I didn't fit, didn't belong, somehow. Grandpa whittled me some toys and things to play with, I remember, but it wasn't like what other kids had. They were pretty poor, I guess, and very religious. As for recreation and things like that, I guess the best times I had were in Sunday School or Church. I really enjoyed myself then, but that's all I can remember about it. I don't know why I enjoyed myself so much in these places."

At 7, N. went to school. He made normal progress, and was considered a fair student from whom nothing spectacular could be expected but who was not an especial problem to his teachers. The town was fortunately situated near a Negro teacher's college, and the enthusiasm and drive of the young aspirants to the profession were communicated to the children in the school N. attended. Hence, they achieved a higher type schooling than most Negro children. The six year course was completed by N. in his 13th year. Although he toyed with ministerial notions for awhile, the need of his grandparents was so obvious that he decided to go to work.

N. obtained employment on a large market farm as a gardener. He was a hard and steady worker whom the owners immediately recognized as trustworthy, and before long he was taken into the home of the wealthy landowner as a sort of second cook. At seventeen, his employer retired and moved north, taking N. with him to a large Eastern city. Soon after this the employer was divorced from his wife, and set up separate quarters in another city. He retained N. as his cook and seems to have had implicit confidence in him. He writes that N. was a faithful employee, even-tempered and generally stable, "although on two occasions I had to get him out of minor difficulties with the police. Once he was arrested for speeding in one of my cars, which I had permitted him to use for marketing, and another time he went on a spree and was detained for disturbing the peace."

When N. was 20, he married a girl whom

he had courted only a very short time. After three months of marriage, his wife confessed to him that she was pregnant by another man. This admission led to a quarrel which eventuated in their separation. N. says of this that he felt betrayed and shaken by the incident, and when his first anger had worn off he set about to find his wife, intending to offer forgiveness and to reunite with her. His efforts to find her, however, were unavailing. In 1941, N. was inducted into the Army.

N.'s military record is clear. He was regarded as a good soldier and was promoted to a corporality after the first nine months of service. Following basic training he was attached to a unit which performed guard duty over stores awaiting shipment at an Eastern port. Meanwhile he met and fell in love with an attractive girl in this city, whom he at once married. They set up housekeeping in an apartment in the Negro section of the town, and for a few months N. was very happy. He believed his wife was devoted to him and was, for a time, secure in her love. It developed, however, that the girl was taking advantage of him. During his absence she entertained other men, was extravagant with his pay, and soon took to berating him for his "lazy Southern ways." Their relationship deteriorated rapidly.

One night N. was returning from duty when his attention was attracted by noises coming from the interior of an Army truck parked near the house in which he lived. As he neared it, he thought he recognized his wife's voice. Lifting the canvas, he dimly perceived a couple engaged in intercourse. Without loitering to make a further investigation, he sprang into the truck, pushed aside the man (who immediately took to his heels), and proceeded to strangle the woman. Only when she was dead did he discover that it was not his wife.

N. reveals that once he had his hands around the woman's throat he could not let go. He says that all the rage and disappointment that had been smoldering within him seemed to overflow and his one preoccupation was to hurt. Later he could not account for this overpowering desire and stated that it was completely foreign to him. When asked whether he had felt that way at the time of his discovery of his first wife's infidelity, he denied it, saying, "No, I was just angry, but I didn't want to hurt her or anything like that."

On investigation it became apparent that the motivation for the murder had its roots in infantile and childhood frustration which the situation re-evoked. N. was threatened with the loss of his love object, with the loneliness which in his early history had driven him to invent a character to share in his life. The response was typically psychopathic—impulsive, primitive, aggressive—utilizing mechanisms which are supposed to be alien to adult life. It was as if all his lifelong striving for regard and affection broke out of bounds in a single agonized protest for the expression of which he was equipped only with aggressive tools. The act of murder in itself was foreign to his personality as we view it now or in the light of his history; but below the surface, awaiting just such an occurrence as transpired, boiled the infantile longing, the threatened withdrawal of which led to murder.

Individual behavior of a psychopathic variety can be understood only through the comprehension of the devious motivational elements which underlie every such act. It seems that a situation is encountered which threatens the organism with a reawakening of the anxiety attached to an infantile conflict between wish and prohibition, and it is the spilling over into catastrophic, eruptive act which we observe. Alternatively to this formulation are the cases in which a psychopathic manifestation is evoked by the situational representation of scenes and events which in earlier years led to a type of behavior which has been repressed by severe cultural and educational training. Here there is no special surge of anxiety, but an understandable and explicable failure of the usual inhibiting mechanisms. The narcotization of the ego and its defenses by alcohol provides numerous examples in this category.

IV. GROUP PSYCHOPATHIC BEHAVIOR

We are not concerned here with the manner in which groups come into being, nor even with those interesting phenomena such as panic and riot. We shall deal, rather, with the dynamics of the transfer of psychopathic impulses from a nuclear origination to persons who ordinarily are free from the type of behavior they demonstrate subsequent to their infection, so to speak, with the pathogenic source. Our case material will be the events of the past two

decades, as well as a unique illustrative occurrence which the writer has had the opportunity to study intimately.

Most of us are capable of keeping our aggressivity under control. Against the primitive urgings of a megalomaniac infancy and the unfulfilled wishes of the first decade, we have erected barriers. By sublimation, reaction-formation, severe repression, and other techniques we have become accomplished in draining the tensions daily living accumulates, in obtaining part-satisfactions, in regulating or adjusting overt performance so that it achieves the appearance if not the reality of conformity. This entails a constant alertness, a moment-to-moment re-adaptation. When, however, and for any reason, the controlling mechanisms no longer suffice, there follows the roll-call of distress, including neurosis, criminality, or psychosis. At such times, the diverted or repressed spills over into symptom or action, depending upon the predisposition of the organism.

The bonds which make for the coherence of a group are libidinal (in the sense of sympathetic or mutual interest) and identifying (in respect of vector orientation toward a person or an abstraction). Hence, it is to be assumed that certain common motivational elements are present in the individual components, and that the personality structures of such components have areas of resemblance. Furthermore, it is again to be assumed that in order for the two foregoing propositions to be realized, there must be some experiential correspondence. And, indeed, if we project for examination such manifestations as, for instance, the spread of Fascism, or the several shirted and anti-Semitic, anti-Catholic, anti-Protestant, or anti-Negro movements here and elsewhere, we discover all of this to be beyond dispute. The tenacious hold which Fascism obtained on the Germans, the Italians, and other peoples was achieved, be it noted, chiefly among the middle-classes, the members of which had been disinherited and dispossessed. These had passed through and been scorched by the aftermath of the first World War, the inflation and the displacement from their accustomed station. They had shared in the common experience of insecurity and anxiety. Moreover, this is similarly true of the underprivileged white who engages in scapegoating techniques in our South, and of the economically insecure and anxious inhabitants

of Northern industrial centers who live under the constant threat of unemployment and in an atmosphere of competition.

In essence, the conditions sketched make for the *anlage* of group psychopathic behavior. The libidinal common-ground cements the group, while from the identifying vector comes the preparatory "set" for the reception of psychopathic precipitants. The separate personalities, then, commonly share similar frustrations, thwartings, desires, and powerful urgings. When exposed to the basic psychopathy of their leaders, they respond psychopathically. What occurs is that, either by design or happenstance, the proper formula for the awakening of the latent psychopathy within the group is enunciated. The formula stirs the infantile sediment which besieges the ego. The image of the leader, as well as his example, is incorporated within the super-ego, thereby weakening it. Direction of the individual personalities is taken over by ancient components, uninhibited by subservience to superego, and governed chiefly by identification with the Ideal ego, the Leader.

The formula for the awakening of psychopathic behavior within the group is amazingly simple. It consists merely of making a direct and forceful appeal to the primitive hungers of infancy, to promise the satisfaction of buried wants, to provide an object for the accumulated aggressivity, and to project as attainable the longed-for autocracy of cradle times. Those slogans which accomplish such aims are familiar to all of us from the Caesarian "bread and circuses" to the incoherencies of the Horst Wessel song.

The prime requisite for the production of psychopathic group behavior is that the leader, the organic centrum of the group, must himself be of psychopathic character. He must conform closely to our sketch of the psychopathic personality, but in addition possess those leadership qualities that have elsewhere been delineated so well. It is from him (them) that the impulse must originate. Evidence for this comes from an examination of historical types, from a knowledge of current leaders, their writings and speeches, and finally from the significant fact that commemorative plaques in testimony to fallen fascist "heroes" are to be found gracing the sites of taverns, dens, and suchlike places.

A highly instructive episode which neatly

demonstrates the essential validity of these propositions regarding group psychopathic behavior was the recent mutiny in the U. S. Federal Penitentiary in Atlanta, Georgia.

In the early evening of a December day in 1944, a unit of the Federal institution in Atlanta was taken over by the inmates housed therein. The custodial officers on duty were confronted by convicts armed with knives constructed of metal scrap and other debris, and were deprived of their keys. The unit was an out-building of the institution that had been designed for special usage and was therefore relatively self-sufficient. A section of it was devoted to the reception facilities and Quarantine housing of new admissions to the institution, while the remainder served as a special treatment section for the management of such inmates who needed to be segregated from the general population for particularized institutional therapy. Those who comprised the latter group were either diagnosed psychopathic personalities, maladjusted and maladaptable characters, or persons who had demonstrated either unadjusted or psychopathic trends. It was an homogenous population in respect of their being Federal prisoners with rather lengthy criminal histories, of possessing established anti-social tendencies, of being unsuited for custody with the rest of the institution's population. Other particulars of correspondence are not important for our purposes here.

Now, the leaders of the mutiny, the original planners, were three in number. One was a sexual psychopath, another an emotionally unstable psychopath, and the third a criminal psychopath. The last mentioned was The Leader. He was the sexual object of the first, and the demigod ideal of the second. This Leader, whom we shall call K., was well-known to this writer, who had examined him two years previous to the mutiny. The psychiatric report prepared at that time was as follows:

The subject's attitude during the interview is slightly antagonistic, although as the interview progresses he becomes warmer in his relationship with the examiner. His stream of speech is coherent and relevant, delivered with unimpaired psychomotor rate. Emotionally he is regarded as highly immature and very unstable, with a predominance of anti-social and aggressive tendencies that have already reflected them-

selves in a long series of disciplinary infractions at the transferring institution. He acts on an egotistical, impulsive level. He is regarded as a great custodial risk, from all points of view, including escape. Emotional responses are cold but fairly appropriate.

His content of thought shows a preoccupation with his own desires and wishes, and an inability to withstand any kind of authoritative control. Sensorium is intact. He is well oriented. General knowledge and intelligence are on an average level. Insight at the present time is completely lacking, and he is obviously a risk as far as judgment is concerned. He is a frontier type of psychopath who has even engaged in the classical crime of cattle rustling. He is aggressive, anti-social, sullen, impulsive, and a disciplinary hazard.

The purpose of the mutiny is not clear. There is some hint in the investigation which was subsequently conducted by the authorities that it was an escape plot, but the leaders have generally denied this. The ostensible aim was to obtain a hearing for the "grievances" which the inhabitants of the unit held against the institutional authorities: however, on examination, these complaints are composed of the usual petty "gripes" and protestations of injustice common in all prison situations, and they are relatively insignificant. The single major item of classification, common to all involved, was the fact that they were housed in the same unit with German prisoners. What is more likely and is, indeed, apparent in the investigation to which the author was made privy, was that the idea of mutiny was a spontaneous readjustment initiating in the three leaders with the design of fulfilling their basal needs and providing real if only transitory satisfaction of stored wants. Subsequent events prove this statement. In what followed the commandeering of the building, K. achieved the power he craved by the bold maneuver; Z., the sex psychopath identified himself with K. and touched off an orgy of homosexual indulgence; Y. destroyed property and energetically drained his tension.

Following the act of appropriation, the three enlisted the cooperation of the other inmates. Exits were barricaded, property destroyed. The unit quickly resolved into a psychopathic society, with its hierarchy of command and other features that write in red letters the frus-

trations and longings of the inhabitants. During the course of the next days, the little society became the means whereby expression was given to the most intimate and repressed wishes. Rapid infection of the whole unit population with the psychopathic virus occurred. The sexually frustrated found outlet in homosexuality, under the supervision of Z.; authority was flaunted, aggression vented, and power exercised by those of K's. type; while the Y's. experienced the widest possible horizons for their talents.

Capitulation and surrender came when the so-called 'demands' were published in the local newspaper. This was the ostensible cause. Actually, the real reason was that the leaders had achieved as much as they could in the face of adamant and unyielding superiority, and the preparations for withstanding a real siege had been pitifully inadequate. What is most interesting to us, however, is the fact that latent psychopathy was communicated rapidly to the extra-unit population. Psychopathically inclined prisoners in the shops and housing units attempted to stir up trouble. They were not successful, mainly because the officials acted with precision to nip these efforts in the bud, and because the population of the rest of the institution lacked the libidinal coherence of the unit and did not identify with the leaders of the mutiny.

Here, in a miniscule and momentary glimpse of group psychopathic behavior, we have revealed the essence of the phenomenon.

ROBERT M. LINDNER,
Haarlem Lodge
Catonsville, Md.

The writer wishes to express his gratitude to Hon. James V. Bennett, Director of the U. S. Bureau of Prisons, and to Mr. Joseph Sanford, Warden of the U. S. Penitentiary at Atlanta, Georgia, for their permission to study and utilize the material herein described.

The opinions expressed in this paper are the sole responsibility of the author and do not necessarily reflect those of the service to which he was attached.

PSYCHOLOGY AND CONTEMPORARY PSYCHOPATHOLOGY.—The years 1926 and 1940 are set as limits to the period discussed. The former marks Kraepelin's death. Until then, psychology's contributions to psychopathology were dictated by orientation—not so much in his psychiatry as in his Wundtian-derived research. Bentley (15) protests that psychology's investigations were made without knowledge of Kraepelin's experimental methods and results. This may have been so—for Wundt himself had noted that the exceptions to psychological laws are more numerous than the agreements and that their significance could be determined only through a study of "characterology," an observation which seems to have been overlooked by psychologists, but which engaged Kraepelin's special attention. So even more regrettably, psychological studies seem to have been made without knowledge of the principles underlying the Kraepelinian systematization of psychiatry. Nevertheless, review was easy; one could, if one wished,—and as Bentley did, limit and simplify the field "by setting aside for a different context most matters pertaining to psychoanalysis."

1940 marks a delineation of the psychologist's frame-of-reference by Allport (1, 2), which will serve as a background for defining the relations of psychology and contemporary psychopathology. Among the accelerated trends are: a striking rise in the employment of statistical aids, the use of animal subjects, the spread of physiological research. "Operationism is the current watchword of an austere empiricism." These, however, do not completely obscure the gropings towards reinstatement of the individual, of the Ego and towards humanism.

For the Ego and intimations of humanism psychology is indebted to psychoanalysis. As Allport (1, 2) puts it, "psychoanalysis marked an inter-regnum in psychology between the time it lost its soul shortly after the Franco-Prussian War, and the time it found it again, shortly after World War I." As Thomas Mann says, "Freud will . . . be honored as the pathfinder towards a humanism of the future."

Two books highlight the situations in 1926 and 1940. The first is W. S. Taylor's *Readings in Abnormal Psychology and Mental Hygiene*. The second is S. S. Tomkin's *Contemporary Psychopathology*. They present striking differ-

ences in viewpoint, aim and content. The authors of 1926 treat psychoanalysis with depreciative consideration;—whereas those of 1943 illustrate in various ways the importance of psychoanalytic theories and principles to the furtherance of psychology's development, especially in the field of psychopathology. An excerpt from H. A. Murray's introduction may enable the reader to anticipate what and what not to expect from the present discussion:—

"Here there are no orderly nosological definitions, no systematic accounts of the diagnosis, treatment and prognosis of every disease entity, no painstaking descriptions of eccentric mental states. Instead you find throughout a ceaseless occupation—speculative, clinical or experimental—with problems of dynamic interaction, of genesis and causation. The participants in this symposium are not so much concerned with descriptions of abnormal phenomena . . ., but with explanations of these phenomena, with the origin of, the development of, the dynamics of, the influence of, the psychogenesis of, this or that particular process or condition."

This suggests that our topic may be envisioned as Psychology and Psychiatry and Psychology and Psychoanalysis. Each sub-topic is a vast one, and I can do no more than to comment on one or more aspects of each.

In psychiatry, psychology still clings to the Kraepelin tradition, at least, to what psychology presumes it to be. This orientation is most clearly and intractably expressed in prevailing methods and hypotheses.

An epitome of the methods is contained in (1) Babcock's (5) *A Scale for the Measurement of Mental Deterioration* and in (2) the various "psychometric efficiency levels for psychotic and age classifications." The former was constructed on the assumption that the vocabulary score is an index of pre-psychotic efficiency, and generalizing from data of study of the organic psychoses, it assigns an organic etiology to schizophrenia or in Kraepelinian terms, dementia praecox. This scale is widely employed in its original or modified forms. The "psychometric efficiency levels" themselves are a modification and extension. These, according to Wittman (87), "cannot be expected to take the place of a specific device for measuring either intelligence or deterioration"; they are intended merely to replace "the subjective and

qualitatively descriptive 'tests of mental sensorium' previously given by the staff physician during the regular mental examination," and "to permit a precision otherwise lacking in mere clinical observation."

The importance of such methods in clinical routine is unquestioned. They are relatively unilluminating and yield no clarifying hypothesis regarding the characteristics of psychotic thinking responsible for the relatively poor performances. Their premises need to be re-examined. For example, Altman and Shakow (4), among others, have shown that the vocabulary performance itself is an imperfect indicator of mental ability; whereas Cattell (21) insists that observation and description must precede measurement and that in these respects psychology has yet to attain the technical level of psychiatry.

An epitome of the hypotheses is presented by Hunt in *Personality and the Behaviour Disorders*:

"We have chosen the term deficit to designate this loss of efficiency because it is a neutral term. Dementia, deterioration and regression, although more prevalent, have become associated with various beliefs about the nature of the loss. Since we prefer to test these various assumptions with the results of investigation, we prefer a neutral term. Deficit has not been associated with any such implications. As used here, it is an operational concept. When any person performs in some situation at a level of efficiency below that expected from comparison with typical individuals or from some indicator in his own present or past behaviour, that person manifests a deficit."

Hunt's aim is "to reduce every aspect of deficit to a truly measurable variable," and he believes that "rate of performance and rate of learning" are "readily quantified by using time as a variable."

Naturally he finds difficulty in reviewing and analyzing the field, more because measurement has so infrequently been preceded by observation and description than for the reasons he gives:

"Unfortunately for the expositor, the studies in this field are not held together with any single purpose or theory. The methods vary tremendously. Rarely has any investigator carried out a consistent program, or even used a single technique, on the whole gamut of clini-

cal conditions. These facts make it impossible to generalize with certainty. . . . We hope, nevertheless, that this chapter . . . will serve as an object lesson concerning the pitfalls of the field. . . ."

And thus he fails to avoid the very pitfalls against which he himself so competently warned in 1929 (53)!

The primary goal of psychology's efforts in psychiatry has been to provide clinical tools as aids in diagnosis and prognosis and—since the advent of shock therapies—evaluation of treatment. Research has been by-passed or been evolved gratuitously, thanks to statistical aids, as a secondary gain.

The procedure is to cut out of the flow of a psychotic's experience a particular phase marked by this or that conglomeration of symptoms. The phase is one of accessibility or cooperation—hence the preponderance of studies of schizophrenics, particularly paranoid schizophrenics. Yet nowhere in psychopathology are there more fundamental problems—and less agreement, since so very few psychologists have been content to evolve methodology from observation and description oriented in the 'known facts' about psychotic behaviour and too many have insisted *a priori* upon "a single purpose or theory." All this constitutes a representative sampling.

The psychotic is then presented with an available test or tests. These were originally constructed for use with the normal and even in the case of the normal their scope and depth in pertinence to measurement of intelligence have been, and are still, being questioned (81). Yet when applied to psychotics, there is not even a preliminary inquiry into the material, formal, and functional aspects (81), or into the ways in which these aspects of tests, especially the functional, prejudice findings. And there is but little appreciation of the fact that tests merely provide clues to the ways in which an individual orients himself to the external world and to himself, to the ways in which he organizes and evaluates his behaviour and the external situation in terms of this orientation. Ignoring the evidences of psychology itself, the patient's performances on tests are transmuted into a score, an index, or a quotient—suggesting that the mental life has but a single dimension.

It is difficult to delineate the frame-of-refer-

ence of this approach except in negative terms. It includes no intimation that:

The world in which the psychotic lives is not the same as the world of which he speaks and thinks, and the world of which he speaks and thinks is not unaffected by the world in which he lives. Krapelin himself denies this possibility when he writes that "the association experiment strikes chiefly at the crystallization of the habits of speech, which are for the most part little influenced by the disorders."

The 'osis' in psychosis, as aptly phrased by Federn (27), refers to the fact that "mental functions which disappear grossly are not lost potentially, or entirely—each function might become temporarily reestablished."

The psychotic is not deceived by the fancied aloofness of the psychologist; at least for him it is not a "detached, objective scientific curiosity. As Eissler (26), among many others, has shown, a psychotic's experiences may be reorganized and reevaluated, again and again, on the basis of "silences," a chance word, gesture, or look, of interest, diffidence or indifference from psychiatrist, attendant, nurse, or attitude and even on the basis of hospital attitudes towards diagnosis, prognosis, and therapy.

Yet all these—and more—enter into the psychotic's test performances! But these and other insights have evolved from the scientific endeavours in neurology and in psychoanalysis, in psychobiology and in psychology itself. Space does not permit review of the fruitfulness and significance of these endeavors. Krapelin-biased psychology manages to escape these insights by avoiding intimate contact with its subject material. It is curious that it can—no one would question Wundt's pioneering the field of reaction time measurement, though he might question his *ex deus machina* self or ego; yet Wundt in speaking of the exceptions to psychological laws and in encouraging the study of "characterology" could only have been referring to the many inner determinants of experience. It is not so curious when we note the statement made in 1908 by Ferenczi (21):—

"The dominance of the materialistic and mechanistic point of view in the nineteenth century first misled psychologists and psychopathologists to renounce the naïve but honest *introspective psychology* and to imitate the experimental methods so successful in the natural sciences. Finally, it went so far that doctors

and natural philosophers handed over as unworthy of their consideration the great and little mental problems of humanity to the writers of *belles lettres*, and confined themselves more and more to the task of the registration of the physiology of the senses. Since Fechner and Wundt, hardly anyone has animated the dead matter of experimental psychology with an in any way informative idea. Freud's exertions have succeeded recently in joining up the broken threads connecting scientific psychology and daily life, and in making a scientific field that had long lain fallow fruitful once more."

In psychoanalysis, if we exclude the efforts of neurology, psychobiology, and even psychology in "joining up the broken threads," we find that—Murray's glowing account notwithstanding—psychology, unhappily, has made little more than a beginning in appreciating the importance of psychoanalysis to its own being. Documentation of this beginning is impossible; it involves reporting upon contributions which have not been labeled as pertaining to psychoanalysis. Instead, we propose merely to intimate how and why psychology has been swept into, shielded away from, or competed with psychoanalytic currents, to indicate the status of the rapprochement of psychology and psychoanalysis—and the forces impeding a more intimate, fused, relationship, to offer suggestions as to strategic points of inquiry and thus—perhaps—to dispel the illusion that there are some problems, if any, that psychology may 'profitably' investigate without reference to theories and principles outlined by psychoanalysis.

"Dreams," wrote Freud, "are particularly fond of reducing antithesis to uniformity or representing them as one and the same thing." Operationism, as *mistakenly* practiced in psychology, is likewise fond. It must be stressed that current operationistic practices seldom correspond to the concept as introduced into psychology by Boring, Kantor, McGeoch, Stevens, and Tolman. It must be emphasized also that these men have not claimed that the values of operationism lie in its *novelty*—Fechner and Wundt's methods were operationistic, as were also Ebbinghaus's (vide his statement of propositions strictly in terms of the measurements employed). If we recall the psychologist's frame-of-reference, we will not be surprised to

find that psychology in psychoanalysis creates antitheses where there are none and reduces them to a single dimension after it has *accepted* what it *likes* and *rejected* what it *dislikes*. With psychology's attitude towards the theory of the dream as an example (50), we note that acceptance is often anonymous and rejection is often in terms of argumentum ad personam. In some instances, acceptance is related either to greater familiarity with psychopathologies or to a deeper comprehension of the theoretical implications of psychoanalysis,—it is not related to priorities or other esoteric issues. Rejection, however, is usually based on sophistries about phantom issues.

A *profile* view of psychology and psychoanalysis serves as the basis for further discussion. Regrettably, it throws into sharper relief the defections of psychology. Consequently, the rejections will be outlined in greater detail. But, happily, these serve to illustrate how decisively the psychologist's frame-of-reference interferes with his realization of the vastness of the problems he ventures to solve.

As in psychiatry, there is a concentration on *clinical psychology*. This was accelerated by Murray's (67) suggestions for the investigation of fantasy and reaccelerated by Frank's article on Projective Techniques. In the latter, the projective techniques were likened unto those of the physical sciences; this analogy, more than anything else, induced many psychologists to become actively interested in methods hitherto regarded as unscientific, mainly because they were deemed unquantifiable, and therefore ignored.

Notable among these techniques are the Rorschach, the thematic-apperception test, and graphology. Beck and F. L. Wells introduced Rorschach's test to American psychologists; Beck's contributions, as well as those of Piotrowski (69), are too well known to necessitate calling the reader's attention to the fact that their significance is not derived from analogies to the data of the physical sciences, but from intimate contact with their subject material. Murray formulated the thematic apperception test, and, as Wells puts it, psychoanalytic insights were undoubtedly involved in raising the Stanford-Binet pictures to the level of a projective technique. June Downey introduced graphology in the form of Tests of Will and Temperament; their derivation from

observations noted in 'classical, academic' experiments and from preliminary observations and descriptions of psychotic patients becomes apparent when one re-examines these tests.

Although the origins of the projective techniques are not grounded in the physical sciences, many psychologists insist upon their meeting the requirements of these sciences. Research seems to center mainly in polemics over the comparative merits of the techniques or in delimiting their applications. Where "operationism" is the watch-word of an austere empiricism the law of parsimony is concentrated upon method and instrumentation and rationale rather than upon theories and principles.

To believe or to insist that any one technique can give a fully rounded picture of an individual's personality, that any one technique is equally informative for all individuals (psychotic, neurotic and normal), or that any one technique is limited to one aspect of the personality (the Rorschach, for example, is supposed to reveal the basic structure, whereas the T. A. T. is supposed to reveal form and content) is to belie familiarity with even Murray's and Frank's formulations. Murray proposes not one but fifteen methods, whereas Frank lists and classifies an even larger number.

Consequently, there is a tendency to ignore the cautions indicated in the literature, especially in the literature pertaining to the T. A. T. Newman, for example, points out that "a single language symptom, though isolated in the descriptive analysis, does not provide a valid point of departure for interpretation"—mis-spelling in one case may mean a revolt against formal conventions; in another it may indicate inadequacy in an activity which the subject regards as essentially adult and beyond his abilities; whereas accuracy may indicate a compulsive interest in carrying out stereotyped performances and in repeating mechanical details. And Balken, in studies employing the Rorschach and the manifest content of a remembered dream in addition to the T. A. T., demonstrates the necessity of considering the dynamics and mechanics of the intrapersonal testing situation in the identifying of variables and in the interpretation and evaluation of findings and finds that the productiveness of even the Rorschach is enriched if evaluated likewise against French's concept of the organization of the individual's behaviour for wish-ful-

filment. The dynamics of the intrapersonal situation have been illustrated in a series of studies with adults and children, psychotic, neurotic, maladjusted, delinquent, or normal; the mechanics refer to features such as the vis-a-vis position, method of recording, and timing. Tentatively, it is found that the "efficiency" of the techniques is a function of the subject's personality and of the investigator's aims. If the latter are exclusively to provide aids to clinical diagnosis, it may be presumed that the Rorschach reigns supreme.

If they are directed towards scientific study of personality, ideally one should employ as many techniques as the limitations of clinical, school or other institutional routines permit and, equally important, the age and sophistication or non-sophistication of the subject. No one technique yields a self-contained picture of personality; sometimes the one supplements and confirms the data of the other, sometimes it gives information which overtly seems to contradict the other—yet these very contradictions are the clues that scientific research seeks to note, describe and classify with a view ultimately to explain. The form and manifest content of a remembered dream is found, tentatively, to parallel that of the phantasies in an as yet clinically undefined group; it is opposite to that of the phantasies in conversion-hysterics—whereas the phantasies are rich, lengthy and absent in manifest anxiety, the dream is filled with terror and inhibition or paralysis of action; and the dream of patients evincing schizophrenic mechanisms is a recurrent one, dating back to a very early age, and often appearing in waking life so that the patient is unsure as to whether it is dream, phantasy or hallucination. The latter tentative finding suggests another orientation for study of the Rorschach and the T. A. T.—it may be noted here that the order of administration is as follows: Rorschach, T. A. T., and a remembered dream. In further exemplification of the supplementary, confirmatory, and contradictory features of information obtained with projective techniques, we cite the case of a 'neurotic' subject whose phantasies were relatively uninformative until related to the Rorschach findings; they then could be interpreted as indicative of an immature ego-development and aided in understanding the narrow range of interests evidenced in a subject whose everyday

interests and information covered ornithology, science, literature, music and the theatre.

There is no need to restate the insights—and their sources—which, as noted above, have been ignored in psychology and psychiatry. It must be stressed, however, that they apply over the whole range of human behaviour—with different emphases in the psychotic, neurotic and normal. What were sins of omission in the context of psychology and psychiatry are sins of commission in this context, since projective techniques are too often applied and evaluated in a professed psychoanalytic frame-of-reference, but, with the support of the analogy to the physical sciences, are assumed to be the "foundation of a new and broader psychometrics" and of "the formulation, on experimental grounds, of psychological theories of personality," where hitherto "most conceptual formulations have come from psychoanalysts and psychiatrists."

Clinical psychology calls for more than passing mention, partly because it is inextricably related to research, partly because the values of the projective techniques are greater than those of clinical methods in psychiatry and hence the hazards are greater. They have an "efficiency" beyond merely lending "a precision otherwise lacking in mere clinical observation." They do not merely supplement information obtained from intelligence and vocational tests; they yield information often only obtainable in the interpersonal configuration of psychologist and subject and may yield information which may anticipate by months that brought out in a psychoanalysis or in psychotherapy. Investigation of the reasons for this is legitimate research, more so than mere accumulation of records; but it must be stressed that information, however illuminating, is not per se therapy.

However, we must pass on to *theory* and *experiment* in psychology and psychoanalysis.

Here, the aims are primarily 'experimental validation' of psychoanalytic concepts and the construction of uniquely psychological theories.

The experiments are so designed as to call for a maximum of peripherality and a minimum of context, content and choice. In short, they are limited to evoking individual peripheral manifestations or processes. "A process . . . is individual peripheral," as defined by Waelder (81), "if it is unaccompanied by internal conflict, as in the case of the satisfaction of certain

needs which are more or less common to all men and approved by the super-ego, and if the means employed in obtaining this satisfaction are known and legitimate." Pickford's (68) study of imagination and the nonsense syllables and Barker, Dembo, and Lewin's (12) study of the PGR to a subliminal tone lead one to doubt that even the 'purest' S-R or 'operationistic' situation is conflict free. Psychology deftly by-passes this in devious ways: it erects barriers and distances—via animals, instrumentation, or paper-pencil—and stop-watch and desk. Over these neither experimenter nor subject dares trespass: this would violate the illusion of 'objectivity' and thus force subject and experimenter to become aware of their mutual involvement in the stream of events labeled 'experiment.'

The theories are often merely transliterations of some illusory, specifically undefined aspect of psychoanalytic theories and principles into the often inimical and obscure idiom of the speculator. Sometimes they are deduced from experiments which create psychophysical or psychobiological organisms and force them to wander as marionettes over the air-blasted, electrified, flat surfaces of Operationism, in the configurations of Gestalt, or in the vector-darted fields of Topology,—and these experiments are presumed to be paradigms of situations encountered in the everyday experiences of psychoanalysis. Sometimes the theories are deduced merely from contemplated experiments. Underlying experiment and theory is the conviction—as William James protested—that no conclusion about human behaviour is quite so scientific as one derived from the twitching of a frog's legs—particularly if the frog is decapitated.

Psychology emerges from experimentation and theorizing in psychoanalysis with a number of doubts, disbeliefs, and convictions—for the ultimate aim, as in clinical psychology, is not merely 'validation,' but the construction of "a systematic psychology of personality," which will "be based on behavior rather than experimental data."

A few psychologists despair that "the sheer testing of psychoanalytic theory is an appropriate task for experimental psychology," and having attempted it, grudgingly admit that the theory does not require validation (74).

In only one instance—and here it must be

remembered that the present discussion pertains only to a *profile* view—is an experiment prefaced by a serious, objective attempt to acquire familiarity with psychoanalytic theories and practices as they have been developed clinically on the human level. The investigator, O. H. Mowrer (66), indicates an aspect of experimentation in this area, which, significantly, has been overlooked by psychologists—namely, its *pedagogical* usefulness, in the sense that “it provides a more general opportunity for first hand contact with clinically discovered phenomena than does the clinic itself and supplies paradigms that may be especially useful as aids to the clearer conceptualization of the psychological principles involved.” It would be wise to extend this attitude to clinical psychology, as well as to experimentation in general.

Psychology insists upon maintaining the fiction of the normal-abnormal antithesis. It clings to a Normal and an Abnormal Psychology. It adheres to the Gaussian code (41). Neuroses are quantitative exaggerations of the normal, psychoses, in turn, of the neuroses. It thus betrays ignorance of the best-developed and best-documented chapter in psychoanalysis (28). It is thus unprepared to realize the implications of the principle that study of the neuroses offers the strategic point of inquiry into the normal and the psychotic and thus cannot fully grasp that the alpha and omega of all psychology—wishes, anxieties (including internal) and the defenses against anxiety—cannot be reduced to a single, linear dimension. It thus ignores even its own evidences accumulated in the course of investigating perception, reaction time, learning, fatigue, intelligence, and so on.

Psychology has no doubts about the justness of its concept of normality. The concept predicates efficiency, but even efficiency is a closed issue—except for formulation presented by Thibaut (77) and premised on Burrows' phylobiology. It is a closed issue, because the “efficiency” of available methods have blinded clinical and experimental psychologists alike to its “artifact” nature. In psychoanalysis, however, the concept has always been a vital issue, not merely a luxury that the moment can or cannot afford,—of importance in both theory and practice. It is invariably woven into the texture of psychoanalytic discussions, especially in those pertaining to character-formations, which, in the long run, emerge from psycho-

logical tests as ‘essentially normal’ and often constitute a goodly number in the tribe from which norms are derived. Currently, the issues embraced in the concept of normality, notably efficiency, are receiving special consideration by Fenichel (28), Glover (41), Hartmann (47), Ernest Jones (57).

But psychology screens itself from its own fundamental problems. The besetting problem, currently, is *frustration*. The theories insist that frustration always leads to aggression; experiments are designed or proposed to prove this hypothesis. Frustration is usually defined in terms of the external situation alone. Nothing is said of the individual's internal reactions to or perceptions of these external situations, or of the more positive and developing effects of frustration in the processes of intelligence and the organization of behaviour. Objective anxiety—albeit camouflaged—at least is being admitted to psychological respectability. Wishes, guilts, internal anxieties and defense mechanisms, however, are still treated as esoteric or as pathologic phenomena. But let psychology speak for itself, via an excerpt from Britt and Janus (19):

“The investigation of *frustration* as a key to the problems of normal as well as of abnormal motivation has been essayed on a number of fronts recently, although its significance was already implicit in the work of G. Stanley Hall and of Pavlov.

“The fruitfulness of the work on this problem is seen in many studies of the past five or six years, including among others those of Anderson, Barker, Dembo, Lewin, Clites, Haslerud, Karn, Liddell, Maier, Mowrer, and Rosenzweig. From a theoretical standpoint, frustration has been heralded as a technique for investigating the nature of the intellectual abilities; as replete with physiological, as well as psychological, implications; and as a factor in lessening the ‘artificial division which now separates normal from abnormal psychology, and abnormal psychology from theoretical psychiatry.’ Nevertheless, caution should be exercised in adopting without qualification certain generalizations such as, ‘creation or growth and frustration or thwarting are merely two aspects of the same life process.’

“It would be difficult at the present time to postulate a definition of frustration that would find ready acceptance among all investigators.

A number of definitions have been advanced, each seizing upon some essential elements of the frustration process to the exclusion of other equally important aspects. However, these will usually be found to have more in common than may at first appear to be the case, with any sins being those of omission. Some criteria of frustration, therefore, may be established even now, albeit tentatively. That is to say, certain limited aspects may be offered to which all judgments relating to the problem can be referred, of course with the understanding that any gaps for which data are as yet wanting may be filled in from time to time as research progresses."

Procrusteanism, rather than operationism, seems to be the "watch-word of an austere empiricism." Without belaboring the question of priorities or the defining of frustration as a process, or even the implications of such Procrustean hypotheses, we present the cautions of Boring that a problem may become stale by the familiarity of the technical language currently used in its statement and solution, that a traditional problem often turns out to be specious when its defining operations are made explicit, and that we cannot assume that the phenomena observed in psychopathology are in any way to be construed as direct evidence of the operation of this, that or another variable.

It is curious that psychology must be so devious and wait on a majority vote. Precise formulations are available in the psychological literature—one needs only to re-read the chapters on learning. They are available also in the psychoanalytic literature and need no longer be extracted piecemeal, as it were, from the context of extensive clinical and popular writings. French (35), for example, defines and outlines orientations for investigation in his analysis of the goal concept as it is based upon study of *reactions to frustration*. The contributions of psychology and psychoanalysis should be *ap-posed*, not *opposed*, for, as French indicates, psychoanalysis' most important contribution to psychology is the demonstration that the psychological laws of rational behaviour apply also to irrational behaviour.

But psychology *rejects* the *methodology* of psychoanalysis as unscientific and hence, as equally unscientific, its theories and principles. Inextricably bound up with this rejection are charges of plagiarism and protests of psy-

choanalysis' indifference to or ignorance of psychology:—

Sears (74), after surveying the 'objective' studies of psychoanalytic concepts, concludes that, according to the criteria of physical sciences, psychoanalysis is not a 'good' science.

Bentley (15) pointedly reminds us that "Free association as a psychological method of research should not be confused with the context of the same term when used to denote the divinatory procedures of psychoanalysis," and, in exemplification, adds:

"The currency of this confusion is illustrated by the remark of F. Alexander that 'psychology, as an empirical science of personality, began with the discovery of the method of free association of Freud.' Everyone familiar with the history of the experimental study of memory and association knows that the method derives from Francis Galton and that it was described in 1879. Galton's object was 'to show how the whole of these associated ideas, though they are for the most part exceedingly fleeting and obscure, and barely cross the threshold of our consciousness, may be seized, dragged into daylight, and recorded.' His method was to allow 'the mind to play freely for a very brief time.' Besides measurable results, carefully described, there came out the emotive, the biographical 'unshared experiences,' the backward references to boyhood, and an intimation of the 'uncharted depths.' Add transference, mechanisms, and speculative theory—the objective and scientifically-minded Galton never would!—and you have Freudian 'analysis.' Before 1890 a whole series of laboratory studies of free associations had been carried out in England and Germany. Alexander finds that 'between 1890 and 1895 Freud . . . discovered the method of free association.' To him that bath!"

Heidbreider (49) asserts that although "Freud's career coincides in time with the rise and development of psychology as an experimental science," his work had the character of "not belonging" and insists further:

"Freud's indifference, furthermore, persisted throughout his career. It remained completely unaltered when psychology itself changed, partly by enlarging its field and including problems similar to his own. The mere suggestion that his attitude might have been otherwise is slightly absurd. It is interesting, nevertheless, as additional evidence of his extraordi-

nary absorption, that a whole new intellectual movement arose and developed in a field presumably related to his own, without arousing his curiosity or even attracting his serious attention." Evidently, the rejection, and so on arises because psychoanalysis can make capital of observations that psychology, with vested interests of a different sort, feels called upon to suppress by dictatorial decree.

At this point, we might interpolate a discussion of the distinctions between scientific temper and scientific techniques (*vide* Bertrand Russell and John Dewey). Instead we merely indicate that the technique, not the methods, of psychoanalysis is unique. Freud, himself, noted this distinction when he states that "the first bit"—turning the manifest dream into the latent dream—"comes under the heading of *dream interpretation*" and requires a technique; whereas the second "... showing how the latter becomes the former in the mental life of the dreamer ..." is a theoretical problem. The technique is scientifically and methodologically adapted to the exigencies of the therapeutic situation and to the complexity of the clinical data (*vide* French). The methods, referred to above as the "mechanics" of the interpersonal situation, are varied accordingly. If one recalls the psychological experiments of "active" and "passive" attitudes or of reaction times and the consciousness or unconsciousness of deception, it will be readily seen that mechanics such as the "couch" position and the "vis-à-vis" are not unique. Failure to distinguish between scientific temper and scientific technique has led many psychologists to duplicate the mechanics as synonymous with the technique. This accounts, in part, for the pitfalls which, for example, directive and non-directive psychotherapies in counseling have encountered.

We indicate further that from Freud and Ferenczi (and Jung) to the present day psychoanalysts have not ignored—as Heidebreider insists Freud has—"imagery and association, memory and emotion,"—"processes of vital importance to the Freudian theories and to the success of psychoanalytic therapy," or "the relationship between cognitive activities and the primal urges." Freud, as late as 1933, expressed his regrets that he did not have the time to acquaint himself with all that had been added to the field of mental science since his first

attempts; he stressed anew that his first intention—and for a long time his only intention—was to understand the disturbances of the human mind and thus he early recognized that "nothing that man makes or does can be understood without the aid of psychology." Space does not permit even mention of other evidences of psychoanalysis' interest in psychology. We call attention, however, to French's (37) contributions to the psychology of learning—the longest and most difficult chapter in psychology and to Flügel's (31) assertion that "the contributions of psychoanalysis to psychology far exceeded those to medical practices."

Somehow, psychology's rejections—stated with varying degrees of triviality and profundity—call to mind the preacher who was, at first, affronted when Mark Twain said that he had at home a book which contained every word of his sermon, then slightly relieved, but still unflattered, when Mark Twain added: "Webster's dictionary."

Psychology's attitude may be partially condoned. Psychoanalysis has experienced three main phases in its development. At first, interest was centered chiefly upon the id. Then came a phase of emphasis on the super-ego. Only recently has it entered upon a phase of emphasis on the functions of the ego. It has been difficult enough for psychoanalysis to keep pace with itself how much more difficult for psychology and how much more confusing now that psychoanalysis is concentrating upon what psychology so foolishly abandoned a long time ago! Moreover, there are discontents even in psychopathology—Glover, for example, notes that there are many who 'hanker after' the fictional normal-abnormal antithesis and a grounding in pure or normal (academic) psychology (41), but that the extent of this desire is in inverse ratio to the amount of positive theory they have been able to evolve from clinical observations, and Schilder (72) notes that psychoanalysis mistakenly feels the need of corroboration from Pavlov's field.

The *defections* of psychology have been purposely exaggerated here in order to indicate the evaluative preconceptions which impede its becoming familiar with the concepts of psychiatry and/or psychoanalytic psychiatry—and which thus impede a more intimate rapprochement. It has been suggested before that *appo-*

sition not opposition be the orientation for rapprochement. It is now suggested that they serve as the orientation for the formulation of problems and the organization of data within a psychiatric-psychologic-pschoanalytic frame-of-reference. Some of the inviolability of the evaluative preconceptions will disappear as psychology finds itself on familiar ground and among familiar faces and thus not compelled to ignore and escape its own history.

Significantly, this orientation brings into sharp relief a large number of important contributions heretofore obscured in the profile view. Passing mention is given to only a very few:—

Vernon's (79) study of the relation of cognition and phantasy which employed tests of apperception and immediate recall to delineate the differences between intelligently directed imagination and phantasy-motivated intelligence on the basis of the performances of school and 'clinic' children.

Cohen's (22) study of the relations of imagery to schizophrenic symptoms which used a modification of a 'classical' questionnaire and had its ultimate inception in the work of Fechner and Galton.

Zucker and Hubert's (90) study of the changes in function found in schizophrenic thought disorders which brought "the problem of schizophrenia, so far as is possible" . . . "into relation with the assumptions which have resulted from the experiments of Beringer and Ruffin in the analysis of function,"—a point of view (figure-ground) introduced into psychopathology by Goldstein, but probably anticipated in the psychologies of Ach and Brentano.

Israeli's (55) studies of the psychology and psychopathology of time-space perception which were derived from his earlier experimental studies of estimation of short time intervals and which bear the imprint of Dodge and Wiersma and Fechner and Wundt as well. Gardner Murphy calls our attention to the importance of these studies for social psychology. Studies of time-space perceptions have so many implications for further research that it is not irrelevant to note French's comment in a review of Thurstone's *Primary Mental Abilities*: "Apparently paradoxical findings such as the discovery of a large S (spatial) factor in a test on sound groupings may even suggest questions that may

lead to the discovery of unsuspected relations." Less clear, but equally pertinent, is Isakower's (54) thesis regarding the 'exceptional place' of the auditory 'sphere': The human being's need for orientation is met by speech, which also is based upon material taken in from the outer world, through auditory 'incorporation', here it is not so much the verbal elements themselves as "the assimilation and correct combination of visual images." And to the time-space perception 'syndrome' Wallenberg (84), hypothesizing from the experiments of Fischer, adds perception of movement (*vide Psychology and Language*).

Space does not permit elaboration of the ways in which imagination is embraced in French's concept of the organization of behaviour for wish-fulfilment. To give texture to the suggestion of the chapters on imagination as the orientation, we refer the reader to Carr's *Text-book* and to Spearman's *The Abilities of Man*. In addition we offer the following:—

Waelder (81) proceeds from the investigations of Head and Goldstein (and Kohler) to demonstrate that aphasias, psychoses, and neuroses may be differentiated in terms of the area in which imagination is disturbed. The world of the aphasic, for example, extends no further than the horizon of his immediate perception; he has lost the category of the 'possible'; his existence is confined to the actual environment at a given moment and to what his vital needs turn his attention to. Thus his freedom of action is spatially, temporally, and attitudinally limited. It is this feature which renders aphasics more amenable to investigation and leads to a greater precision of prediction as to his future behaviour. Goldstein (43) subscribes to this view and it is not surprising to find him stating confidently that "we have progressed so far toward constructing the total picture of the patient that we can predict with relatively great certainty how he will behave in any situation, even in respect to tasks which we have not yet examined." In fact, Goldstein's formulations regarding the disturbance in imagination anticipated Waelder's. The world of the psychotic, in contrast, has no horizons; he cannot escape the accidentals of a given situation and thus for him everything is possible; all these 'possibles' are terrifying—at first he tries to 'prove' that they are 'real,' thereby increasing

the fears, and ultimately may seek refuge in 'escape from reality.' His freedom is thus less limited than that of the aphasic, but experimentation with him is correspondingly more difficult. The neurotic's, and the normal's, conception of the 'possible' is overly realistically oriented and too much dictated by the coercion of the past which is betrayed in devious ways and intimated in wit, dreams, and lapsus linguae. His freedom is limited in proportion to the magnitude, and concentration in a level of psychological development, of the coercion of the past. Needless to note that, in research and clinically, he is more of a dark-horse than the aphasic or the schizophrenic or even the child.

Reik (70) demonstrates the ways in which imagination is differentially expressed and organized in the neuroses. His observation on neurotic camouflage and thought rehearsal may have bearing upon the elucidation of the psychological content and function of the primary mental abilities, notably V, W, and R: "The forces of intellect are enlisted to such an extent in the highly and ingeniously complicated way in which the obsessional patient weaves his ritual into the texture of reality situations that one can not conceive of a dullard remotely achieving the adroit 'stage management' required for the camouflage."

Another writer suggests that eidetic imagery may play an important role in obsessional acts and ceremonies. Forsyth (32) notes that the capacity of the child for projecting vivid 'mental' images, especially in the dark and when alone, is one of the most important reasons for the almost universal childish fear of the dark; this suggests an explanation of the reactions of young children to the Rorschach stimuli. Eidetic imagery may play a role in 'hypnotizability,' which has been frequently investigated by the Rorschach method. Kluever's (62) studies are significant in this context as suggested in the following excerpt:

"We recall that in eidetic images and certain other phenomena we find translocation of objects or transfer of certain characteristics of these objects or transfer of certain characteristics of these objects, fusions, and composite formations, substitutions, the appearance of parts instead of wholes, the nonappearance or the belated appearance of objects or parts of objects, reversals of right and left, up and down, or of

other direction. In other words, we find condensation, displacement, and other mechanisms that have been considered typical of dream formation. In eidetic individuals, similar changes may occasionally appear in the perception of real objects and thus become more easily amenable to an experimental approach. From various studies, it is evident that phenomenal properties of objects, visuo-spatial factors, and motor factors play a great role in effecting condensations, displacements, and similar changes in eidetic imagery. *This suggests the possibility that the changes in dreams such as condensations and displacements, frequently result from an operation of the same visuo-spatial, motor, etc. factors.*"

Bally elaborates upon the ways in which psychoanalytic theories and principles acquire new illumination from Jaensch's experiments and theories. "Under the influence of the transference situation," for example, "the patient returns to the eidetic level of experience and through the vivid pictorial recall of early infantile experiences under more favorable conditions, the ego is able to so alter the super-ego that command of the personality is gained and adaptation to reality attained."

Other trends such as those revealed in a series of lectures on imagination, including one by Gerard on the bio-physical basis of imagination, suggest the fruitfulness of this orientation for a fusion of psychiatry, psychoanalysis, and psychology. However, the issues so hotly contested by psychology are apt to be terminologically camouflaged unless it heeds and extends the cautions which Thurstone (78), points out in an article on Current Issues in Factor Analysis:—

"The investigator who wants to use factor methods must be competent in the science whose problems he wants to solve." "My own contributions to factor analysis have been motivated by a desire to solve some fundamental problems in psychology, and consequently I have tried to discourage a tendency to regard the factor method as a self-contained and extraneous statistical procedure. Its logic must be dictated by the nature of the scientific problems which it is intended to solve."

PSYCHOPHYSICS.—Psychophysics is that branch of psychology which deals with measurement in the subjective or experiential continuum. It deals with two large classes of problems, namely, those which are concerned with liminal or subliminal differences between stimuli that can barely be differentiated and those which are concerned with supraliminal differences between stimuli which are judged as to their degrees of dissimilarity. The objects which are so studied are called psychological objects, which may be any persons, ideas, symbols, or things about which the subject can judge that "A is x 'er than B" where x is any designated attribute. The attribute about which the subject makes his judgment may be called the primary attribute while other attributes that are not explicitly judged may be called secondary. The physical stimulus continuum is defined by a series of stimuli that differ sequentially in some specified attribute. A corresponding subjective or experiential continuum is defined by the sequential qualities or processes by which the physical stimuli are experienced and overtly differentiated. For any given modality the dimensionality of the subjective continuum is equal to the number of independently differentiable attributes in the adequate stimulus continuum.

Historically, psychophysics has been concerned with several relatively simple problems, namely, the experimental study of liminal differences and Weber's law, the experimental study of supraliminal differences and Fechner's law, and with experimental methods of limen determinations which describe the sensitivity of the subject.

WEBER'S LAW

One of the central problems in classical psychophysics is concerned with the experimental and analytical methods of estimating the limen of a subject. This is a physical measure of the smallest stimulus increment that he can perceive. Weber's law is frequently stated in the form $\Delta I/I = k$, where ΔI is the smallest perceptible stimulus increment, I is the stimulus magnitude in some primary attribute, and k is a constant. This common formulation of Weber's law cannot be operationally interpreted without introducing ambiguities. When the subject discriminates, he does so in differentiating two stimuli. In a limiting case, where

the threshold is the object of study, one of these magnitudes is zero, but this case is not usually of importance for the experimental verification of Weber's law. The law should specify something about the subject's discrimination between two stimuli whose magnitudes should be explicitly denoted. Further, the subject fluctuates in his ability to discriminate. Hence we should state Weber's law by specifying the relative frequency of correct discrimination which shall constitute acceptable performance. Restating Weber's idea in experimentally meaningful terms we can write it in the form $P_n >_{kR} c$ where R and kR are the two stimulus magnitudes which are presented for discrimination, k and c are constants, and P is a proportion. A revised statement of the law then declares that the proportion of correct discriminations between R and kR is a constant for different values of R . Weber's ratio is then $(1-k)$ if the constancy of c can be shown experimentally.

Weber's law can be verified for a variety of stimuli but it has definite limitations. It is not verified near the threshold; nor is it verified for high magnitudes approaching the terminal values. Weber's law is further limited to stimulus series in which the stimuli are of uniform discriminational dispersion (defined below). It has frequently been assumed that equally often noticed differences are subjectively or psychologically equal, but this theorem is also limited to stimuli of uniform dispersion. A set of stimuli can be so constructed as to satisfy Fechner's law but not Weber's law. This can be done because Fechner's law is not affected by variation in discriminational dispersion whereas Weber's law is so affected.

FECHNER'S LAW

Another large section of traditional psychophysics has been concerned with the relation between the physical stimulus magnitude and the corresponding subjective or discriminational continuum. In order to make this comparison each stimulus magnitude must be allocated to the discriminational continuum. A simple and direct method is to present the subject with two stimuli and to ask him to produce or select a third stimulus which seems to him to be experientially midway between the two given stimuli. This is the method of mean gradation. The three stimuli are then considered to be equidistant on the discriminational continuum and their physical

magnitudes can be determined. The subjective magnitudes of the stimuli are denoted S and their physical magnitudes are denoted R (from the German word *Reiz* = stimulus). It has been found that when S is plotted against R , the relation is usually logarithmic and hence it is described by the equation $S = k \log R$ which is known as Fechner's law. In this equation k is constant. The origin for the subjective scale S is the scale value of a stimulus of unit magnitude $R = 1$. Hence negative values of the S scale represent stimuli whose magnitudes are less than the physical unit chosen.

In psychophysical experiments it is desirable for the subject to judge the experienced magnitude of the stimulus as distinguished from estimation of the physical magnitude of the stimulus. A grocery clerk who has practice in estimating the weights of packages might find it difficult to serve as a subject in a psychophysical experiment in the stimulus range with which he is familiar. To the extent that the subject is estimating physical magnitudes instead of comparing subjective qualities, he commits what Titchener called the stimulus error. Some students of psychophysics have been concerned about this problem.

PSYCHOPHYSICAL METHODS

In most psychophysical problems the two stimuli to be compared are presented either simultaneously in different parts of the sensory field or successively in the same part of the sensory field. In either case there is the possibility of a constant error which can be classified as a space error or a time error.

The greater part of the older psychophysical literature was devoted to limen determinations. A limen is that stimulus magnitude which the subject is just able to perceive. A difference limen is that stimulus difference which the subject is just able to perceive.

The most complete and fundamental of the psychophysical methods is the *method of paired comparison* in which each stimulus is compared with every stimulus. If there are n stimuli in the series, there will be n^2 comparisons in a complete schedule of presentations. If the stimuli are of such a nature that the identity of a stimulus is easily recognized by the subject, then it cannot be compared with itself and there remain $n(n-1)$ comparisons. If complete counterbalanced order is not retained, then only one

of the two permutations jk and kj is used, and there are then $n(n-1)/2$ different paired presentations to the subject.

Because of the labor of presenting a set of n stimuli in all possible pairs, the procedure is frequently simplified by using only one stimulus as a standard. This standard stimulus is compared with all of the other stimuli and this makes a total of n or $(n-1)$ paired presentations to the subject. This simplified procedure is all that is required when the only purpose of the experiment is to determine somebody's limen at the stimulus magnitude of the standard. This procedure is called the *constant method* which is a special case of the more complete method of paired comparison.

In all psychophysical experiments in which two stimuli are presented to the subject for comparison, the experimenter must decide whether to give the subject two or three categories of judgment. If only two categories of judgment are allowed these are $j > k$ and $j < k$. If the two stimuli seem to the subject to be equal, he is not allowed to say so. The subject is requested to make a definite judgment as to which of the two stimuli is the greater in the primary attribute even if the judgment is a guess. If the subject is allowed three categories of judgment he has the privilege of giving one of three judgments, namely, $j > k$, $j < k$, $j = k$. There is frequent confusion as to when the intermediate category of judgment is to be allowed. The decision depends on the purpose of the experiment. If the purpose is to determine the subject's limen, i.e., his ability to discriminate, then only two categories should be allowed even if the two stimuli seem to him to be equal. If the purpose is to allocate each of the stimuli to the subjective continuum, then only two categories should be allowed. If, on the other hand, the purpose is to study the experience of equality, then the intermediate category should of course be admitted and even encouraged. The reason for this restriction is that some subjects require a high standard of certainty before they deviate from the equality judgment whereas other subjects with different temperaments will readily make assertions about the stimulus differences when these are slight and uncertain. The use of the intermediate category of judgment confuses the limen determination by introducing temperamental characteristics in what is fundamentally a problem

of sensitivity and discriminatory ability. It has been shown experimentally that the proportion of judgments $p_j >_s$ is a continuous function of R_j for a given standard R_s even when the range is very small. The proportion of correct judgments is higher than chance even when the subject says that he is merely guessing. The intermediate category could be used in the study of temperament but that possibility has not yet been adequately explored.

Another psychophysical method is the *method of limits* in which pairs of stimuli are presented. One of these is always the standard stimulus. The variable stimulus is presented first at a very low value and its magnitude is augmented in steps for the successive presentations. At first the subject reports $j < k$ where j is the variable stimulus and k is the standard. When the variable comes close to the standard the subject shifts to the judgment $j = k$. When the variable stimulus has been raised to a higher magnitude the subject changes to the judgment $j > k$. The value of the variable stimulus is noted at each shift in judgment. The same procedure is followed for a descending variable stimulus, starting with a magnitude well above the standard. In this manner there are determined four limens, namely, lower ascending, upper ascending, upper descending, and lower descending. Because of a lag in the change from one category to the next, it is characteristic that the two ascending limens are higher than the descending limens and the lag can itself be an object of study with possible relations to the temperament of the subject. The several limens obtained by the method of limits are usually pooled into a single average limen for the subject.

The method of *mean gradation* consists in asking the subject to find a stimulus which seems to him to be midway between two presented stimuli. This method differs fundamentally from the previous methods in that we are here dealing with supraliminal stimulus differences whereas in the previous methods the presented stimuli differ mostly subliminally. When the method of mean gradation is extended to a larger number of steps, it becomes the *method of equal appearing intervals*. Here the subject is asked to assign a number of stimuli to a set of intervals in such a manner that the intervals seem to him to be equal. It can be shown experimentally that the subject usually fails to accomplish these instructions so that the inter-

vals at the ends of the scale are subjectively larger than the intervals in the middle range. The instructions can be altered so that the stimuli are sorted into a set of successive intervals without restriction that the intervals shall seem equal to the subject. This is the *method of successive intervals* in which each interval may be denoted by a sample stimulus or by a descriptive phrase, depending on the nature of the material to be discriminated. A limiting case is the *method of single stimuli* in which a descriptive phrase is given to each stimulus without a perceptually available standard. Another method is that in which the subjects are asked to place the stimuli in *rank order*. From the rank orders by a group of subjects, it is possible to compute the proportions $p_j >_s$ and these in turn give the scale values of the stimuli as in the fundamental method of paired comparison.

The *method of reproduction* is perhaps the simplest method. Here the subject merely tries to reproduce a given standard stimulus. The absolute error is measured for each attempt and an average error of observation can be computed.

THE PSYCHOMETRIC FUNCTION

In making limen determinations by the constant method, the data are expressed in the form $p_j >_s$ where j denotes variable stimulus and k denotes the standard. These proportions are plotted against the variable magnitudes R_j and the result is a sigmoid curve which is asymptotic to the base line at the left and to the value $p = 1$ for high values of R_j . This curve is known as the psychometric curve. A number of numerical determinations can be made from this curve. For example, the constant error is the stimulus increment between the value of the standard R_s and the value of R_j at the ordinate $p = .50$. If the stimuli are subject to an illusion, then the constant error measures the amount of this illusion in terms of the physical scale of stimulus magnitudes. The limen is, similarly, a physical measurement which may be defined as that stimulus difference which the subject differentiates in, say, 75 per cent of his attempts. Related measurements can be derived from the psychometric curve such as the interval of uncertainty, the point of subjective equality, the upper and the lower limens.

Much attention has been given to the problem of curve fitting for the psychometric function but these attempts represent usually nothing but empirical equations. At one time it was found that \tan^2 gave a good fit but the probability integral has been found preferable. It has been named the *phi-gamma hypothesis*. This is merely the well known S-shaped curve of cumulative frequencies for a Gaussian distribution and it can be fitted by the procedures that are conventional in statistics. It can be shown that if Weber's law holds, or any other law according to which the limen is some monotonic increasing function of the stimulus magnitudes, then the psychometric function must be positively skewed. Since it is a universally admitted fact that for most kinds of discrimination the limen is covariant with the stimulus magnitude, it is impossible for the psychometric function to be symmetric as required by the phi-gamma hypothesis. The reason why the positive skewness of the psychometric function was not discovered in early studies was that they were concerned with relatively fine discriminations where the skewness was not noticeable. For coarse discrimination the positive skewness of the psychometric curve becomes conspicuous. Recent studies by Rekesy and by Stevens have demonstrated linear psychometric functions for discriminations of relatively simple attributes, such as pitch and loudness, which sustain a quantum hypothesis in discrimination. For discrimination of stimuli where the primary attribute is itself physiologically complex, it is likely that the psychometric function is S-shaped. It will usually be symmetric when $p_1 > a$ is plotted against $\log R_1$.

EXTENSION OF PSYCHOPHYSICS TO SUBJECTIVE VALUES

The application of psychophysical methods to the problem of limen determinations has been one of the central themes of classical psychophysics. Its only reference to the psychical is the implication of a subjective increment that is just differentiable. The subjective continuum is implied in the methods that involve supraliminal comparisons as in the method of mean gradation and its variants. Classical psychophysics has been concerned with liminal differences in determination of limens and in the experimental verification of Weber's law and

with supraliminal differences in studies of Fechner's law. As long as psychophysics was thus limited in its range of psychological application it was a rather sterile part of psychological science and it has justly been so regarded by most students. The outlook for psychophysics changes entirely when we extend the subject to the differentiation between things that are more important, both scientifically and socially. We are then concerned with the projection of a stimulus series on the subjective continuum. Further, instead of limiting psychophysical studies to those stimuli for which there exists some physical measure of the attribute to be differentiated (length, weight, brightness) as in testing Fechner's law, the methods can be extended to the study of differentiation among psychological objects for which the primary attribute does not have any known physical measure. Psychophysical method must then supply criteria of internal consistency so as to satisfy the logical requirements of measurement as distinguished from rank order. The unit of measurement becomes then a subjective process.

Consider a set of stimuli which have been arranged in rank order according to some primary attribute. For illustrative purposes, let this attribute be physically measurable such as length or weight. The process by which the subject perceives a stimulus may be called the *discriminal process* for that stimulus on that occasion. A comparison of two stimuli will then be determined by the gradient between two discriminational processes. A stimulus is not always experienced by the same discriminational process which fluctuates from one moment to the next. That process by which a stimulus is most frequently experienced by a subject may be called the *modal discrimininal process* for that stimulus. Each discriminational process may be similarly identified theoretically as the modal discrimininal process for some stimulus. The discrimininal processes may be considered completely unknown as to their physical or psychical nature. Let all the discrimininal processes in terms of which a given stimulus is experienced be spaced on a subjective continuum in such a manner that their frequency of association with the given stimulus is Gaussian. Such a subjective scale is completely arbitrary if it is defined by only one stimulus. Let all of the discrimininal processes be similarly allocated for a whole stimulus series. Then it becomes a question of

experimental fact whether the several scales are identical so that the proportion of judgments $p_1 >_2$ agree with the theoretically expected proportions. Each stimulus is then defined in terms of two parameters for the subjective continuum, namely, its scale value which is the scale position of its modal discriminial process, and the standard deviation of the dispersion which each stimulus projects on the subjective or experiential continuum. The standard deviation of the projection of a standard stimulus may be defined as the unit of measurement for the whole stimulus series. This may be called the *discriminal error*.

This formulation of the problem leads to the law of comparative judgment which in its complete form is

$$S_1 - S_2 = x_{12} \sqrt{\sigma_1^2 + \sigma_2^2 - 2r_{12}\sigma_1\sigma_2}$$

in which S_1 and S_2 are the subjective or experiential scale values of the two stimuli as to the attribute by which they are compared, σ_1 and σ_2 are their respective discriminial standard errors, and r is the correlation between the discriminial deviations of the two stimuli. The value x_{12} is determined from the probability tables by the experimentally observed value of p_{12} , which is the proportion of the subjects who judge that $1 >_2$ in the primary attribute, or the same proportion for repeated trials by one subject. If the two stimuli are not subject to contrast effects or similar disturbances, the correlational term vanishes and the law then takes the simpler form

$$S_1 - S_2 = x_{12} \sqrt{\sigma_1^2 + \sigma_2^2}$$

This law expresses a relation between the scale values, the dispersions, and the experimentally determined values of x_{12} . The check for internal consistency is in extensions of the principle that the experimentally observed separation ($S_1 - S_3$) must equal the sum of the two experimentally observed separations ($S_1 - S_2$) and ($S_2 - S_3$). The experimental verification of this law does not depend on the physical measurement of the stimuli and it is therefore applicable in the measurement of values that have no known physically measurable counterpart.

The extension of the psychophysical methods with the law of comparative judgment and the appraisal of scale values as well as subjective

dispersions makes it possible to extend quantitative studies that are truly psychological to a great variety of problems. These include the laboratory measurement of discrimination of complex stimuli as, for example, the comparison of noises as to their pitch. Social attitudes of individuals or groups of subjects can be studied quantitatively before and after propaganda without any physical measurement of the propaganda stimuli. Moral values are similarly the subject of quantitative investigation such as the comparison of seriousness of crimes. International attitudes can be studied in several variant forms by psychophysical methods. International attitudes have been studied by these methods in the analysis of newspaper editorials over a period of years. When the scale values and dispersions are known, we can make predictions about the number of subjects who will choose any designated psychological object as their first choice. These theorems have application in the prediction of political elections and in studying consumer preferences to predict sales. In experimental aesthetics the new psychophysical methods have another application so that aesthetic theory can be brought into the laboratory for quantitative study. If the designated attribute is itself ambiguous and not rigorously defined, the psychophysical methods enable us to study the variation in connotation of a symbol in any particular group of subjects. The new methods are therefore applicable in semantic studies. Extensions of these methods have been made that enable us to define experimentally the zero point in an affective continuum where positive values represent appetition and negative values represent aversion. The utility concept in economics is similarly measurable by psychophysical methods.

The psychophysical methods are applicable to any set of psychological objects which may be persons, ideas, or things, about which the subject can make the comparative judgment that one psychological object exceeds another such object as to any designated attribute.

PSYCHOSES,* THE.—The term "insanity" or "psychosis" is ill-defined, amorphous in meaning, and of little practical value. It is primarily a social term. The definitions vary according to: (1) the lay opinion, (2) the legal definition, and (3) the medical concept.

The lay definition is particularly vague, varying with the person using the term and with the situation. In general, society holds as "insane" those actions which are markedly inappropriate to the situation. The concept of "appropriateness" (cf. Latin *proprius*, proper) will vary with the time and locale; and men will mockingly and half seriously accuse as "being crazy" anyone who deviates from customary social practice. When the inappropriate action is occasional and without understandable emotional basis, the involved person may be termed "queer" or "eccentric." When the inappropriate response is constant or exaggerated, the lay diagnosis of insanity is made. In a primitive society which believes in witchcraft and "voodoo," one who sees ghosts or who has visions of spirits is not considered "insane" because his responses are "appropriate"; in a modern, highly organized social unit, such a person would be made the subject of psychiatric examination. History shows countless examples of such men as Pasteur, Fulton, and the Wright brothers, whose assertions were regarded as so out of keeping with "normal" and "customary" experiences as to be labeled as "madness." In other words, any action or any person who is *too* "different" from the accepted pattern is considered "insane."

The legal definition of insanity in the United States is archaic and without basis either in terms of customary social definition or in terms of scientific knowledge. In many law courts of the United States, the test of insanity is whether a person knows the nature and quality of an act and knows whether it is wrong; that is, whether he can distinguish right from wrong. In some states, a further qualification is added that to be sane a man must be able to refrain from doing that which is wrong, and have the capacity to resist an impulse.

These legal definitions have resulted in unjust verdicts and sentences. Feeble-minded persons are not "insane," yet often fail to distinguish between "right" and "wrong." Many normal

persons in certain situations cannot make such a distinction; while, on the other hand, many obviously psychotic patients can verbally make this legal distinction. The terms right and wrong are, in themselves, so vague in definition as to render the test invalid.

Furthermore, many so-called nervous persons (psychoneurotic) are so subject to compulsions that they are "unable to refrain" from doing "wrong." Even normal persons may, under the influence of "normal" anger, commit acts which they know are wrong, and for which only technically can they be termed as insane.

In consequence, the legal definition of insanity in the United States is valueless, and should be replaced by the more scientific, medical concepts of cause or of disease pattern.

The medical definition of the psychoses is a generic one, and includes a number of relatively unrelated disease processes. The "psychoses" (Gr. *psych*, soul; and *osis*, disease) cannot in many cases be sharply differentiated from the psychoneuroses, from psychopathic personality reactions, or even at times from normal responses. From a medical aspect, the term psychosis acquires specific meaning only when defined as a serious personality disorder of specific etiology or of definite pattern.

There are two main categories of psychoses: (1) the Organic Psychoses and (2) the Constitutional Psychoses. By definition, the organic psychoses result from physical disease of the brain and are evidenced primarily by disturbance in intellectual ability. The constitutional psychoses are, according to the consensus of psychiatric authorities today, on a constitutional basis and are subdivided into two widely different personality patterns: (a) the manic-depressive psychoses which are primarily disturbances of mood, and (b) the schizophrenic psychoses, which are primarily disturbances in the associative processes of thinking. These psychotic patterns differ widely in their symptomatology.

In consequence, it may be said that there is no sharply definable entity, "the psychoses." Instead there are several types or kinds of personality response which, to be clearly conceived, must be labeled in accordance with their etiology or symptom-complex.

HISTORY

Our present concepts of the psychoses have been developed primarily since the 19th cen-

* Condensed from *The Therapy of the Neuroses and Psychoses*, Lea & Febiger, Philadelphia, 1943.

tury. Prior to that time not only was medical classification faulty, but the reaction of society to these patients was largely a matter of local superstitions. In many earlier societies, epileptic and psychotic patients were regarded as being possessed of the devil. Accordingly, they were burned at the stake, beaten to "drive the devil out," and otherwise tortured in the guise of therapeutics. Frequently such patients were regarded as dangerous and were confined by steel chains in dungeons, and they were mistreated by brutal and ignorant gaolers. In other times and lands, these patients were thought to be in possession of special attributes and abilities so that one could curry favor with the gods by propitiating the "madmen." For the most part, the average psychotic patient was not recognized as "being sick," and so when he could not be cared for at home was confined to the "poor house" or to jail. Medical care was rarely sought.

Gradually various institutions came into use for the exclusive care of these patients. Bethlehem Royal Hospital (Bedlam) in London (founded as a priory in 1247) was rebuilt as an asylum for the insane in 1676. In 1725 a Rhode Island (U. S.) law permitted towns to build houses of correction for vagrants and also for "mad persons." Custodial institutions opened elsewhere throughout the civilized world, the care being given these patients frequently varying with the financial means of the family. In the United States private institutions were opened (psychotic patients were admitted to Pennsylvania Hospital, 1752; the Hartford Retreat, 1824; Dexter Hospital, 1828; Butler Hospital for the Insane, 1847); and in 1773 (incorporated in 1768) at Williamsburg, Virginia, the first public institution, now the Eastern State Hospital, was opened for the insane. Conditions in the rest of this country did not improve for many decades; and the work of Dorothea Dix (1802-1887) in fostering the establishment of well-cared-for medical institutions marked a great forward step.

The medical concept of the disease developed gradually. Felix Platter (1602) described four types of mental disorders: (1) *mentis imbecillitas*, (2) *mentis consternatio*, (3) *mentis alienatio*, and (4) *mentis defatigatio*. T. Willis (1674) described "clinical entities" under the heading of stupidity and morosity. Late in the 18th century Phillipe Pinel (acting against the

advice of his colleagues who warned him that he was taking his life in his hands, freed patients from the heavy chains which bound them in their stone cellars), stimulated the medical world to a newer and more humane concept of this illness. The French school tended to classify psychotic patients primarily into the degenerate and the non-degenerate groups, without any clear cut divisions of psychotic illness as we know them today. The English school grouped these patients into the "mania-excitement," and the "melancholia-depression" classifications which included many of the organic psychoses, and the schizophrenias. The German school evolved the concepts of *amencia* and *Wahnsinn* (*Wahn*, false; *sinn*, sense; i.e., acute, non-systematized delusional and hallucinatory states), paving the way for the Kraepelinian conceptions.

In 1863, Kahlbaum attempted to define specific medical entities and not merely give descriptions of psychologic syndromes. He advanced four large groups of disorders: (1) *vesania* (*ve*, not; *sanus*, sound), or general insanity, which had four stages ranging from melancholia, through mania and confusion, to dementia (cf. *dementia praecox*); (2) *vecordia* (i.e., wrong-heartedness), representing the "emotional" psychoses and much of the pattern today called the manic-depressive psychoses, but also including even the "monomanias" of the French school; (3) the dysphrenias (*dys*, ill; *phrenia*, mind) resulting from toxic-exhaustive disorders; and (4) the paraphrenias (*para*, distorted; *phrenia*, mind), or age-determined disorders, including the neophrenias of infancy, the hebephrenias of youth, and the presbyophrenias of old age. These concepts held sway for a while but did not stand the test of time.

In 1851, J. P. Falret had described "*la folie circulaire*" which later became our present manic-depressive psychoses; and E. Kraepelin in 1887 (further developed in subsequent editions of his text-book) formulated the present concept of *dementia praecox*. Bleuler later (1916) coined the term *schizophrenia* as a concept differing only slightly from Kraepelin's *dementia praecox*. Adolf Meyer (1922) views the psychoses not as disease entities but as reaction patterns to pluralistic causes.

This evolution of psychiatry from the initial purely descriptive levels, then as a definition of symptom complexes in terms of prognosis, and

finally to the delineation of syndromes which show a unity of cause, course, and conclusion has still not reached the final stage. The work of Freud has done much to help us understand the psychologic mechanisms, but we are only in the initial phases of understanding the etiologic mechanisms of the "constitutional" psychoses.

THE ORGANIC PSYCHOSES

The organic psychoses, though of varying etiologies, have one factor in common: a physical disturbance of the cerebral cortex. The symptoms of these psychoses result not from the specific nature of the cause; for many dif-

ferent conditions can similarly disturb the functions of the cortex. Hence, the psychotic symptoms of such widely varying diseases as senile dementia, general paresis of the insane, and alcoholic psychosis are essentially the same, the differences lying primarily in the physical signs. The psychotic symptoms fall into two categories: intellectual symptoms and personality changes.

The pathology of the organic psychoses is (1) always present in the cerebral cortex, and (2) is diffuse in its involvement. There are many instances wherein the subcortex has been injured or diseased without any resultant impairment of "mental faculties." Thus apoplexy,

CHART No. 1

Movement of Patient Population in State, Veterans', County and City, and Private Hospitals for Mental Disease, by Type of Control of Hospital: 1941

Movement of Patients	All Patients			Private Hospitals	Percent of All Patients			
	Total	Male	Female		State	Vet- erans	County & City	Private
Patients on books at beginning of year	542,477	292,345	250,132	11,406	85.8	5.8	6.3	2.1
In hospital	480,741	259,616	221,125	10,588	85.1	6.2	6.5	2.2

* Patients in Mental Institutions, 1941, U. S. Department of Commerce, Bureau of the Census.

with hemorrhage in a large area of the sub-cortex, only rarely produces a psychosis. Parkinson's disease with deterioration of the basal brain ganglia is rarely associated with intellectual deterioration. When psychotic symptoms do result from such subcortical disturbances, they are usually secondary to retrograde nervous degeneration or to circulatory changes involving the cortex.

That to produce psychotic symptoms the organic pathology must involve rather large areas of the brain can be seen from the fact that local hemorrhages in the cerebral cortex, small cortical tumors, and even penetrating wounds of the skull do not produce a psychosis. The exact extent of the brain which must be involved before personality manifestations are produced is unknown, but it is established

large areas must be involved (cf. Lashley's experiments on "mass action" of the brain). There are, moreover, specific areas of the brain which, when disturbed, will give rise to special symptoms. Thus, an injured "speech area" may bring about aphasic symptoms, and injury to the "visual area" will produce an agnosia. On the other hand, injury to and even removal of large portions of the frontal lobes may leave the person with an intact and seemingly normal personality.

The disease processes which affect the brain fall into five categories: (a) toxic, (b) infectious, (c) degenerative, (d) traumatic, and (e) neoplastic. In some of these conditions, the brain is involved directly, as in the degenerative psychoses; while in others, the disease process may exist elsewhere in the body and involve the brain secondarily, as in the toxic state accompanying pneumonia. The symptoms of all the organic psychoses fall into three categories: (1) physical symptoms, (2) intellectual impairment, and (3) personality changes.

THE PHYSICAL SIGNS AND SYMPTOMS

The differentiation between the different types of organic psychoses must be made primarily upon the physical signs rather than on the mental changes. There may be such general changes in the body as are seen in the toxic states of pneumonia and other acute infectious diseases of the body. There may be such specific symptoms as alcohol on the breath in the alcoholic patient, or bromide in the blood of the patient with bromide delirium. There may be involvement of the physical nervous system as evidenced by the pupil and reflex changes in the general parietic patient. The senile-dementia patient will manifest all the signs of aging changes in the blood vessels, skin, muscle, etc. These physical changes due to the disease process are essentially the main evidences of the etiologic agent, and together with the history of the illness are the basis for specific diagnosis.

INTELLECTUAL IMPAIRMENT

Although we lack a precise definition of thought and its dynamics, it may be assumed that without the cerebral cortex, thought, as commonly understood, would be impossible. A corollary to this premise is that thought is most efficient in a "healthy" brain; and conversely, a

disturbance in the physical functioning of the brain is associated with an impairment in the efficiency of thinking.

The patient with an organic psychosis has primary disturbances, therefore, in his thinking process. This disturbance may be extremely mild, and detectable only by intimate associates of the patient, or may be gross and patent to the casual observer. The whole thought process is involved, with those functions of mentation requiring the greatest training being the first to suffer.

Although various intelligence tests may be used, the standard psychiatric practice is to examine the patient as to: (1) his memory for recent and remote events, (2) his orientation as to time, space, and persons, (3) his general information at the time of the illness in contrast with his knowledge before the illness, (4) his ability to calculate, in relation to his educational background, (5) his judgment as applied to standard test stories, or to current situations, and (6) his insight as to his deviation from normal behavior. The questions asked of the patient under each of these headings vary with his cooperativeness, his alertness, his span of attention, and his previous intellectual attainments. Thus the average grammar-school graduate would be asked to perform some simple addition; whereas the former college professor of mathematics would be given an algebraic problem. Any coexisting factor which influences the patient will alter the test responses. The purpose of such examination is to determine the fact and degree of loss of intellectual ability.

In the mild case of organic illness, the first observable changes of intellect occur in memory. The patient becomes somewhat forgetful, misplaces common and everyday objects, cannot recall names or dates, overlooks appointments. Judgment is not so keen as formerly, and decisions become hesitant. As the illness progresses, the memory becomes more and more faulty. The patient may forget what he wished to purchase at the store, he may be unable to recall what he had for breakfast, he may forget the name of the street on which he lives, he may not recall the names of his children or even whether he has any children. He may become confused in his actions and may be unable to dress himself, he may eat soup with a fork, or pick at his meal with his fingers.

Simultaneously, he deteriorates in his appearance and in social behavior.

These intellectual changes, varying from the almost undetectable to the extremely obvious confused state, are characteristic of the organic psychoses, and irrespective of the nature of the disease are the result of injury to the cerebral cortex.

PERSONALITY CHANGES

Although the personality is altered, *ipso facto*, with the deterioration of intellectual ability, an additional group of personality changes occur which result from the emergence of the underlying basic personality (cf. Hughlings Jackson's release of "lower" nervous centers with disease of "higher" centers). As indicated by Kretschmer, Jung, and others, there exist at the extremes of the distribution curve fairly definite personality types. Some persons are characteristically shy, sensitive, withdrawn, and, in Jungian terms, "introvert." At the opposite end of the scale, are those persons who are socially active, full of humor (or its counterpart, anger), aggressive, and "extrovert." Between these extremes are the vast majority of persons with combinations of these opposing (or rather antithetical) characteristics. In all persons, there is further modification of this "basic" personality by neurotic and psychopathic features.

Modification of behavior is possible by means of the cerebral cortex. In animals without the cerebral cortex, conditioned reflexes, the simplest forms of behavior, are almost impossible (cf. Pavlov). Because of his cerebral cortex, the human animal has been able to control, redirect, inhibit, and sublimate fundamental drives and reaction patterns. In those cases where the person's actions seem uncontrolled, as in psychoneurotic or psychopathic states, the responses, though unhealthy and immature, are nevertheless the product of cortically controlled psychologic dynamisms.

When there is a physical impairment of the cerebral cortex such as occurs in disease, there is a resultant disturbance in the function of that cortex. Hence, not only is there a loss of the intellectual powers of the cortex, but there is interference with the processes of inhibition, sublimation, and control of drives and reaction patterns. Those elements of the personality ordinarily held in check by cortical action will

then emerge. Rarely will they emerge in pure form because complete cortical control is lost only in coma or death, and because the basic reaction patterns have been modified over years of training; but the greater the degree of loss of cortical function, the greater the release (in the sense of Hughlings Jackson) of the basic personality.

Thus, the general parietic patient who has always been shy and sensitive, withdrawn and introvert, may present, in addition to the signs of intellectual damage, symptoms of schizophrenia. Another patient with general paresis may present signs of manic illness with overactivity, euphoria, grandioseness, and a flight of ideas. A third patient with this form of syphilis of the brain may be depressed, tearful, taciturn, and suicidal. A fourth patient suffering from the same disease, may present the personality symptoms of a neurotic, with hypochondriasis and symbolic complaints. In such case, the etiology has been the same, but the underlying personality has been different; hence there is a different form of personality response. The same principle holds true for all the organic psychoses. The differential diagnosis can be made primarily through the physical aspects (and clinical history) of the disease.

The etiology of the disease is relatively unimportant in the production of these "release" symptoms. The determining factors are the severity and diffuseness of the pathology, the amount of disturbance in the brain cells. Thus, the same amount and kind of intellectual loss, and the same personality symptoms may be present in a patient who suffers from general paresis, from chronic alcoholism, from bromide intoxication, or senile dementia. On the basis of the psychosis, and in the absence of knowledge of the physical status, one would find it almost impossible to make a differentiation between these various etiological agents.

Acute disease of the brain cells presents a different clinical picture from that produced by chronic disease. The relatively sudden and intense involvements of the brain tend to be short-lived; they are termed the Acute Deliria. The chronic diseases of the brain differ not only in that there is less intensity of irritation of the brain, but in that there is greater opportunity for the total personality to make readjustments to living. Accordingly there is a diminution in the intensity of symptoms de-

spite destruction of large amounts of brain tissue.

In the acute states, the patient seems much more ill physically, is more confused intellectually, is usually more fearful and emotional, and often has sense falsifications.

THE ACUTE PSYCHOSES (Acute Delirium)

Acute disturbances of the brain may occur as a result of such direct infection of the brain as meningitis or encephalitis, or as a result of toxins arising from an infection elsewhere in the body. There is relatively little, if any, difference between the psychotic symptoms of the various deliria, the determining factor lying not in the etiologic agent but in the extent and intensity of the pathology. There is also a second factor of "constitutional resistance," so that one patient with a given amount of cerebral pathology may manifest few symptoms; whereas a second patient, with the same amount of physical change in the brain, may be acutely delirious.

In mild cases, the only evidence of delirium may be transient, mild, and barely noticeable forgetfulness and irritability. In severe cases, there may be acute physical illness, intense confusion and disorientation, marked fearfulness, with shouting and uncontrolled activity, and eventually convulsions or coma. The average case occurs after some physical illness while the patient is in the hospital.

The patient at first seems weak and apathetic. Usually, the appearance is that of fever or exhaustion. Laboratory tests will often indicate a toxic or infectious state. The patient becomes more restless, the muscles jerking, or twitching, or moving about purposelessly. In severe illnesses, the patient will attempt to get out of bed and move about the room. Sometimes the struggle to get out of bed becomes acute, and it may be necessary physically to restrain the patient.

The patient's intellect suffers. A state of confusion supervenes, characterized primarily by lack of orientation and memory defect. At first the patient does not recognize the doctors or nurses, and then may not identify friends. Even the names of close relatives may be forgotten. The patient may not remember the day or the month or even the year. He may not know the name of the hospital, or know that he is in a hospital. He hears instructions and expla-

nations as if he were in a dream and then asks some question or makes some statement which indicates that he has not understood what was said. He is disinterested, and his attention is captured by passing stimuli, though only momentarily. His judgments are without value primarily because of the memory defect, but also because the highest developed intellectual functions, in this case the discriminatory ones, are the first to be involved in any brain disease. Formal tests indicate that his knowledge of general information is defective, and that his ability to calculate is poor.

The personality symptoms will vary with each patient. A state of fear is present in most patients. In the mild state, it may be easily alleviated by reassurance and a quiet, competent nurse. In acute instances, the fear may become intense, so that the patient is fearful of anyone who comes into the room, is fearful of the food that is given, is afraid of the medicine or the nursing attentions. Sometimes, actual panic states may develop, with the patient struggling violently in an effort to escape the room.

Other personality symptoms may occur depending upon the emotional state of the patient before the illness, and upon his basic personality. Some patients may have a manic reaction, with laughing, punning hilarity. Others may be depressed, crying, hopeless, and even suicidal. Some may become suspicious, and develop delusions and hallucinations as in the schizophrenic. Still others may become markedly hypochondriacal.

Illusions and hallucinations may develop in the acute psychotic reactions. The basis for these symptoms lies in at least two factors: an impaired apperception, secondary to the disturbance in the cerebral cortex; and a toxic stimulation of the sensory nerves. In the first instance, stimuli are not immediately and correctly identified, and are misinterpreted. Thus, a passing shadow may be interpreted as a stranger entering the room, or a waving curtain may appear as a burglar coming in the window. The stimuli are interpreted according to the gestalt of the person at the time, so that if a state of fear exists the stimulus will be interpreted accordingly.

The second factor in the production of illusions and hallucinations lies in the irritation of the sensory nerves by the circulating toxins. The nerves, thus stimulated, send impulses to

the cerebral cortex, and there are interpreted according to the degree of excitability of the brain cells and the existent gestalt. Such stimulation of the visual hallucinations is commonly seen in delirium tremens in acutely toxic states. If the auditory nerves are involved, mere "noises" may be heard if the toxic condition is mild; whereas voices of a terrifying and accusing nature will be heard if the disturbance is great. If the sensory nerves from the body are excited, there may be feelings of skin irritation "as if ants were crawling on the skin" or there may be sensations of "electricity." Such sense falsifications are much more common in the acute psychotic reactions than in the chronic ones.

THE CHRONIC PSYCHOSES

In this group of psychotic disturbances, the etiologic agent acts much more slowly than in the acute reactions, so that the symptoms usually require a much longer period of time for their full expression, and the personality has an opportunity for partial readjustment to the environment. The psychotic symptoms in this entire group depend primarily upon the pathology and site of involvement instead of on the etiology. Since the psychotic symptoms are so much the same in the various subgroups, only one disease process characteristic of each of the infectious, toxic, and degenerative classifications will be described. The psychoses associated with trauma (0.5 per cent of all first admissions) and neoplasm (0.2 per cent) are relatively infrequent and will not be described here.

GENERAL PARESIS

There are several types of syphilis of the brain, but only the meningoencephalitic form produces a psychosis. This form (known as general paresis because before the advent of modern therapy the patients became completely paralyzed in the end stages) is the result of an invasion of the cortex of the brain by the spirochete, *treponema pallida*. Until recent years about 8 per cent of all first admissions to mental hospitals were general paralytics. The disease is found about five times as frequently among men as among women. It has been estimated that about 1 in every 200 syphilitic patients will develop this kind of infection of the brain. Usually, the mental symptoms do not manifest themselves till 15 to 25 years after the

initial infection so that the majority of cases are found in men over 40. However, there are cases where the new-born child may have congenital syphilis in which the brain is involved.

The disease process is so slow that chronic brain changes are found. The membranes about the brain are thickened; the brain shrinks to two-thirds its normal weight and size; the cerebral convolutions are shrunken, especially in the frontal area; and microscopically one finds many dead and dying ganglion cells. Scattered throughout the brain spirochetes are found.

The symptoms of general paresis may be described in three categories: (1) The physical signs are primarily those of neurological syphilis. The patient may appear in good health early in the disease, but will be wasted and pale later. He has headaches which shift in location. The pupils have the well-known Argyll-Robertson sign wherein the pupil of the eye is small, irregularly shaped, and will not react to light though it will react to accommodation. (That is, the pupils of the normal eye become smaller when light is thrown directly into them, and they will also become smaller when a person shifts his gaze from a far point to a near one.) There are tremors of most of the muscles, including those about the lips, the tongue, and the hands. Writing with pen and ink demonstrates marked tremulousness. As a result of disease of the cells which control the movements of the muscles of speech, the patient is often unable to pronounce words containing several syllables, such as "constitution," "rough riding artillery brigade," or "sinister similarities." Epileptic attacks may occur because of brain irritation. Aphasia may occur if the speech area of the brain is involved. In addition, signs of involvement of the spinal cord are present, manifesting themselves in disturbed reflexes, if mild; and in tabetic paralysis, if severe. Tests of the blood (Kahn and Wasserman) and of the spinal fluid (Lange gold curve), all show definite evidences of syphilis. If no treatment is given, paralysis of all muscles sets in and the patient may die of the slightest illness.

(2) Symptoms of intellectual deficiency are usually the first to make friends and relatives aware of the disease. Inasmuch as these symptoms develop over a period of years, the first signs of the illness are often overlooked. At first the patient is forgetful, not recalling the

names of his friends, forgetting his routine tasks, misplacing items, making appointments and then not remembering them. At the same time there is a defect in customary judgment, seen particularly in men who have responsible positions. The controlling influence of the cortex is diminished and cautiousness is succeeded by impulsiveness, snap judgments, impatient decisions. As the disease progresses, the memory changes become more marked and the patient becomes acutely bewildered in his own accustomed office or even home. He may forget what street he lives on, what day or even year it is, what the names of the members of his family are. He cannot perform the simplest additions or subtractions even in getting change from the corner store. He recalls nothing of the current events, and becomes completely confused about subjects concerning which he may previously have had the strongest of convictions.

(3) Personality disturbances occur simultaneously. Sometimes these changes are relatively mild and the patient will sit about showing no change other than apathy and loss of intelligence. In other instances, the personality changes produce a marked conflict with the environment. The cerebral cortex, having lost or having diminished directing power, has less control over the person's response to irritating situations. Consequently emotional responses become common, and violent outbursts occur over insignificant unpleasantnesses. For the same reason—that is, diminished control by the cortex—the slightest pleasures create enormous good humor, and whims of appetite are excessively indulged in. At least seven distinct psychiatric states may result, depending upon the basic personality and its modifications: (1) Simple dementia, wherein physical and intellectual signs predominate and where there is the mildest of personality disorder. (2) Manic or euphoric states with the patient extremely happy, full of greetings for everyone, expansive, and giving away millions of dollars or strings of pearls. (3) Depressive states wherein the patient will be unhappy, morose, silent, inactive, and suicidal. (4) Agitated depressions with the patient not only depressed but restless, full of anxiety and fears. (5) Schizophrenic states with the patient having many delusions and hallucinations; feeling persecuted and becoming withdrawn. (6) Psychopathic states wherein latent

sadistic tendencies may come to the fore, and (7) psychoneurotic types with many physiologic tension symptoms and multitudes of symbolic reactions.

These psychiatric states may occur partially or in full-fledged form. They may occur singly or in combinations. The entire emotional background of the patient furnishes material which may be woven into the existing psychiatric pattern. There is no single personality state which is characteristic of general paresis.

The treatment of this condition falls into two categories. The first is directed along anti-syphilitic lines, with the use of fever-producing agents (it is interesting that in tropical countries, where both syphilis and malaria are present, there are very few cases of general paresis—showing the effect of fever on this disease), arsenical, bismuth, and mercury drugs. Recently, penicillin has been reported as having a remarkable effect in clearing up syphilis. The second form of therapy is in the custodial or psychiatric care which is given concurrently with the medication. Sometimes electric shock therapy is necessary in addition to the anti-luetic measures.

Most investigators have found that under treatment one-third the patients recover, one-third the patients improve, and one-third the patients do not get well.

Other chronic infections of the brain will produce a similar symptom complex, depending on the intensity of the brain infection.

THE ALCOHOLIC PSYCHOSES

The alcoholic psychoses do not occur in all persons who are chronic alcoholics. There is a marked variation in individual tolerances to alcohol. Some persons can drink large quantities of alcohol without any permanent and with but mild transient effects, while others become acutely intoxicated with small amounts, and develop liver and brain degeneration relatively easily.

There are many degrees of alcoholic psychosis. From a technical aspect, drunkenness is an acute but brief alcoholic psychosis. It is temporary and reversible, but nevertheless its symptoms are similar to those of the delirium of a pneumonia, or the psychosis of bromide intoxication. In such cases, the alcohol reaches the brain cells and decreases their ability to function. (One must consider separately the influ-

ence of small amounts of alcohol in releasing inhibitions and permitting an increased output of energy and emotion.) The physical symptoms of thick tongue, staggering gait, etc., are familiar. The intellectual symptoms are proportionate to the amount of cortical involvement: the memory is impaired, and actions may be performed about which there will be no recollection on the next day. Judgment is interfered with, and the entire sensorium performs at a lower level of efficiency. Here again the personality symptoms vary according to the underlying personality and the emotional state of the person. Thus some persons become excessively good-humored and extremely loquacious when intoxicated; others become suspicious, sullen, morose and ready to "pick a fight"; still others begin weeping and reciting all their miseries; and so on.

If enough alcohol is taken and the person is susceptible, coma will finally result. However, since the body can metabolize this drug quickly and since alcohol itself has only the mildest of effects on the brain cells, permanent effects are rarely found in the occasional drinker.

In persons who drink heavily over long periods of time the brain cells do not have time or opportunity to recover from each alcoholic episode. After a varying time, the brain cells cannot return to their normal state; and a more chronic form of alcoholic psychosis will occur—delirium tremens. In this mental state, there are similarly the three phases described above; in addition, the toxic condition of the visual nerve results in the setting up of impulses which are interpreted and colored by the brain as visual images or hallucinations. As a result the patient "sees pink elephants," snakes, flames, etc., depending upon the emotional gestalt at the time and the toxicity of the cortex. The patient is acutely ill physically at this time, and death is not uncommon.

Where the basic personality is of the shy, suspicious type, instead of the typical delirium tremens there may develop an *alcoholic hallucinosis*. In this condition, the toxic effect on the brain does not differ essentially from that of the delirium tremens, but the personality reaction does. Hallucinations and delusions are marked. Patients appear to be almost definitely schizophrenic and are often so diagnosed when the antecedent history of alcoholism is not known or when it clears up quickly. The more

severely disturbed the personality, the less the amount of alcohol necessary to bring about this condition.

Under proper treatment with vitamins, insulin, rest, and occasional drainage of spinal fluid, most of these conditions can be cured. The brain cells for the most part have not been permanently damaged.

As the alcoholic addiction continues, however, the brain cells become less and less able to recuperate and finally a more or less permanent psychosis occurs. There are variations of this final condition variously described as *Korsakoff's syndrome* (which has marked polyneuritis associated), *alcoholic pseudo-paresis* (where the symptoms appear very much as those of the general parietic patient), *alcoholic encephalopathy* (with associated paralysis and damage to various nerves), *chronic alcoholic deterioration* (with signs of complete intellectual dementia). In all these conditions there are disturbances in the three spheres initially described: (1) physical changes, (2) intellectual deterioration, and (3) personality changes. Unfortunately, once a brain cell has died it cannot be replaced or restored; and in these latter alcoholic states, therapy is of only partial value.

There are many other toxic states which produce reactions similar to those induced by alcohol. These include delirium from such drugs as bromides, arsenic, and mescaline; delirium associated with infectious diseases in parts of the body other than the brain, such as pneumonia, typhoid fever, streptococcal throat, etc., and toxins from internal disturbances, such as hyperthyroidism and uremia.

SENILE DEMENTIA

The cells of the cerebral cortex may be damaged by the aging process. The age at which brain cells begin to die varies with each person. Heredity plays an important role; and lack of vitamins, fatigue, associated disease, and arteriosclerosis complicate the picture. Senile states most commonly begin after the age of sixty-five, though they are absent in many persons much older and appear in many persons much younger. On examination of the brain in advanced cases of senile dementia, one finds it shrunken in size and with many brain cells "missing." Physically the person has all the signs of aging. Intellectually, there is the gradual loss of memory and associated intellectual

processes. The process of deterioration is so slow, however, that many persons can readjust their habits and manner of living to an acceptable but less efficient social level. In advanced cases, the patient may forget the names of his children, may leave the house in which he has lived for many years and not be able to find his way back, etc. Finally, there are varying degrees of personality changes which range from the extremely mild and hardly noticeable to the marked and socially disturbing ones. In some persons, irritability becomes marked, paranoid tendencies develop, depressive episodes occur with suicidal drives, and even manic excitements may be present. These extreme personality disturbances require special hospitalization and care. Much can be done prophylactically for the aged by attention to diet, vitamins, type of work done, social activity, etc.

THE MANIC-DEPRESSIVE PSYCHOSES

The manic-depressive psychoses are a series of so-called mental reactions which are characterized primarily by marked acceleration or deceleration of psycho-physical activities. Because of the marked changes in mood (either exaltation or depression) this illness has often been termed a disorder of affect. Clinically, there are variations from the normal not only in (1) mood, but also in (2) psychomotor activity, and in (3) speed of thought and speech.

The symptom-complex is considerably modified by such psychologic dynamisms as are found in the neuroses, the psychopathic states, and in schizophrenia. The manic-depressive response is also frequently found as a "release mechanism" in the organic psychoses (q. v.).

ETIOLOGY

The primary cause of this psychosis is unknown. Clinical impressions lead many observers to conclude that there exists a definite constitutional predisposition.

Heredity plays an important role. However, evidence of the extent of its influence has not as yet been brought forward. The vast majority of patients who have manic-depressive reactions are not hospitalized, and, indeed, are often unrecognized as suffering from such illness. In consequence, statistical studies of the heredity factor involved do not present a complete picture. In practice, one finds in the forbears of these patients frequent histories of depressive

like episodes, of suicides, of prolonged illnesses of unknown origin, etc.

The typical physical physique of these patients emphasizes the constitutional elements of this disorder. There are many general references to the relationship of physique and temperament, but Kretschmer formulated this status more clearly. Most of these patients (84.6 per cent according to Kretschmer; and 69, 71.4, 76.4 per cent according to three other authors) have a pyknic physique. The pyknic person tends to be of average or slightly below average height, has a round face, narrow shoulders, a broad trapezoid thorax with an obtuse costo-sternal angle, a round protuberant abdomen, fleshy limbs, small joints, little head hair after the age of thirty, and marked secondary sex distribution of hair. The cardiovascular system is on the larger side of normal.

Most of these patients have a characteristic pre-psychotic personality. They are "extrovert," being highly sociable, aggressive, dynamic, dealing with facts realistically, and are often good-humored. This "basic" personality may, however, be considerably modified by environmental pressures and psychic traumas.

The most frequent age of onset is the fourth and fifth decades of life. However, any age may be affected. In general, it can be said that the manic reactions occur later. Women suffer much more frequently than men, and "for the period from twenty to thirty-nine years the rate among males is less than half that among females" (Pollock). In general, the rate in cities is greater than that in the country. The average annual admission rate to state hospitals is about 7 per 100,000 for males, and about 11 per 100,000 for females.

Environmental stress and psychic trauma have often been mentioned as etiologic factors in individual cases. Yet in most cases there is no demonstrable stress; or the stress which is given as a cause is so mild as to be relatively non-disturbing in the average person, and has usually been non-disturbing in the patient on previous occasions, and will be equally unimportant on occasions subsequent to the illness. Moreover, some patients will develop a manic attack following a "psychic trauma"; while others, with similar disturbances of environment, will develop depressive attacks. Recovery from the illness is spontaneous and often without any change or improvement in an emotion-

ally disturbing environment. Most investigators agree that the psychologic factors do not play the primary role in causation.

Spontaneous recovery from this illness is the rule. The attacks last from a few days to several years; but the average range of illness is of a cyclic nature, so that the depressive attack is followed by a manic episode, which in turn is again followed by a depressive attack, and so on.

A further indication of the physiologic nature of this illness is the response to convulsive (shock) therapy. Depressive patients will often recover in a short period of time under such physical treatment, whereas psychoneurotic patients are rarely improved by this therapy.

Despite all these indications of the constitutional nature of the illness, modern pathologic methods have still been unable to uncover any organic disease. It is probable that the source of difficulty will be found in "functional" physiology rather than in the "structural" pathology.

NORMAL LEVELS OF PSYCHOPHYSICAL ACTIVITY

In order to follow the psychotic mood changes it is of value to review similar changes within the "normal" or average person. Each person has a level of psychophysical activity which is characteristic of him. Again, for purposes of description, this theoretic level is divided into three sublevels: mood, psychomotor activity, and speed of thought. The composite of these three levels fits within the range of a normal distribution curve for members of society, so that at one end of the scale there are persons with a high level of mood, a large amount of spontaneous psychomotor activity, and a great rapidity of thought and speech. At the opposite end of the scale are persons still "normal" but with minimal amounts of each of these characteristics. Between these extremes are many persons who have combinations of these three qualities at different levels, so that one person may be "happy" most of the time, while having lesser amounts of physical response and relatively slow thought processes; while another may be of a "melancholic" temperament and yet have high levels of energy and a rapid stream of ideas. Yet, whatever their level, these three personality functions tend to remain characteristic of the person throughout his life, although modifiable by environmental situations.

In the "norm," this psychophysical level is influenced by pleasure and pain, in that there is an elevation in mood (and the other psychophysical levels to a lesser degree) with the advent of a pleasurable stimulus and the converse with an unpleasant stimulus. Everything else being equal, the response, in either direction, will be proportionate to the strength of the stimulus. There are obviously innumerable factors which enter into the reaction of a complex personality; but in principle these positive responses to pleasure and negative responses to pain (in its broadest sense) are relatively short-lived, so that the individual person returns to his former level within hours or days after the stimulus. Where the stimulus is continuous, as in encouraging or discouraging environments, or where there are special psychologic pressures and associated neurotic responses, the psychophysical level may be somewhat elevated or depressed for longer periods of time before return to the customary level. There is a "normal" or average social range for these mood variations in the "normal" person.

In the manic-depressive psychoses, there is such marked elevation or depression of this psychophysical level as to create an *ab-normal* state. There is no definite border between the normal response and the abnormal one; and there are degrees of change in level from the feeling of cheerfulness to the acute maniacal excitement, and from the mild "blueness" to the intense suicidal depression. The manic-depressive response differs from "normal" responses to stimuli in: (1) intensity of reaction, and in (2) prolongation of reaction. The psychotic response is measured by society in terms of intensity and prolongation of response as compared with that of the average person; but medically the psychotic response must be measured in relation to the usual and characteristic psychophysical level of the person.

THE MANIC PSYCHOSES

Because of the variations in the intensity of the manic response, this reaction pattern will be discussed under three headings: (1) Hypomania, (2) the Manic Attack, and (3) the Acute Delirious Mania. The divisions among these groups is for clinical purposes; and it is impossible sharply to delineate the borderline cases from each other or from the "normal" response. These patients have various degrees

of: (1) euphoria, (2) hyperactivity, and (3) acceleration of thought and speech.

THE HYPOMANIC ATTACK

The patient who develops a hypomanic illness has a "greater-than-usual" elevation of his psychophysical level. During such a phase, he begins to "feel" more cheerful than usual. Ordinary incidents of the day, which used to depress him, now seem to be of only passing concern. He finds himself whistling, singing, or humming without any particular reason. His outlook upon life becomes optimistic and radiant. He laughs easily and often excessively. He is full of good humor and witticisms. Feelings of "inferiority" are lost and everything seems possible to him.

His psychomotor activity increases. He is constantly in motion, not in the tense, restless fashion of the anxiety patient, but with free movements. He hurries from one place to the next, jumping up from his desk, calling on the phone, talking to one person after another, all with a seemingly inexhaustible store of energy. These patients may carry on their activities till late at night, and after a few hours' sleep awake refreshed, charged with more energy. Their whole organism seems to be operating at a more efficient level. Their digestive processes are excellent, and even old persons "look young."

Speed of thought and speech increases. Solutions are arrived at rapidly and, if the hypomanic attack is not excessive, often correctly. They talk continuously, and with brilliance and wit. Most of their responses tend to be superficial because of the constant change from one topic to another. The "goal idea" changes frequently, and several ideas may be expressed in rapid succession. They are easily stimulated and distractable, noticing all things in the environment and commenting thereon. Brilliant and daring schemes are conceived and often set into motion if the person has a position of authority. His intellectual restraint is weakened, and he becomes presumptuous and overly aggressive. He may be moved easily to anger, and usually returns quickly to a state of forgiveness.

The entire clinical picture, irrespective of actual age, is that of a bubbling, overactive youth, with no restraints, who is constantly in action, constantly talking, and full of enthusiasm.

This reaction pattern may last from several weeks to several months and then be followed by a return to normal level. Often the patient, and indeed his friends, notice nothing abnormal other than that he appears to be unusually happy and active. Rarely are there psychological or environmental stimuli of adequate intensity to give rise to such a response. The illness comes on spontaneously, and disappears in similar fashion. In many instances, such a "psychotic" personality reaction results in a "better" personality than the "normal" one. Its abnormality lies in the fact that it is an uncontrolled over-response (i.e., overly intense and excessively prolonged) of the usual psychophysical level.

In other instances, such a hypomanic attack is succeeded by a comparable decrease below the basic level—and there results a depressive state of comparable intensity. In still other cases, the hypomanic attack is of short duration and is prodromal to a typical manic attack.

THE MANIC ATTACK

The manic attack differs from the hypomanic only in intensity of symptoms. Occasionally a short-lived depressive period is present before the onset of this acute attack. The patient's mood is that of euphoria. His feeling of exaltedness is extreme, and his overestimation of his abilities leads to the diagnosis of "grandiose delusions." He sings loudly, shouting at the top of his voice. He becomes intensely active physically, running, jumping, playing with tremendous amounts of energy. He cannot be retained in his usual social position or work, because of this pressure of activity. His thought processes become so speeded up that one sentence runs into the next; his thoughts seem to have no sequence; and he comments on everything he witnesses (distractability), often without completing the intended comment. The pressure of speech may become so intense as to produce a "flight of ideas." In his calmer moments, he may be witty and sarcastic, but usually the flow of talk is rambling.

This high pitch of activity is not constant but fluctuates within the day and within the cycle of the illness. Rage and anger may be present, and even tears may occur momentarily. During these periods the patient's intellectual ability remains normal, and he is oriented, has good memory, ability to calculate, and a good

grasp of current events. Only in the intense states is there a "clouding of consciousness."

Recovery usually occurs spontaneously in from several weeks to several (three to six) months. There are many variations in the duration, from the fleeting manic attacks which last a few hours to the chronic, lifelong attacks. In many instances the recovery can be hastened by shock therapy. During the illness most patients need to be confined to institutions. After the attack has disappeared the patient may return to a normal status or may develop a depressive reaction.

THE ACUTE DELIRIOUS MANIA

As the name implies, in this phase the patient becomes so intensely active that a deliriouslike state develops. The patient may actually die of overactivity. He is so intensely disturbed as to be not only uncontrollable but confused and hallucinating. Drugs are for the most part of little value in quieting the patient. This condition is an intense manifestation of a manic attack, and the symptoms subside if death from exhaustion does not supervene.

THE DEPRESSIVE ATTACKS

The depressive phases also vary in intensity from (1) mild depressions through (2) acute depressive states and to (3) depressive stupors. The depressions are further complicated by (4) the changes occurring during menopause, resulting in involuntal melancholia; by (5) emotional tensions, leading to agitated depressions; and by (6) psychoneurotic complications, giving rise to neurotic depressions. There is also that group of depressions, (7) reactive depressions, in which the mood response seems appropriate to an extremely disturbing situation. These subdivisions differ primarily not in kind, but in intensity of depression and in the presence of complicating organic or psychologic factors.

THE MILD DEPRESSION

The mild depression, like the hypomanic state, is often unrecognized either by the patient or by his friends. The onset is gradual, and the patient "feels blue." He becomes more than ordinarily inclined to worry about small incidents, and each responsibility or assignment seems like an insurmountable task. He becomes pessimistic and feels unwell physically.

The face expresses anxiety and fatigue. The patient is easily moved to tears.

An almost pathognomonic symptom complex appears. These patients find it (1) difficult to sleep, and (2) awaken tired in the morning. They (3) lose their appetites, and food seems tasteless; (4) weight loss is common; (5) constipation is frequent. There is a (6) loss of sexual libido. (7) Interest in current events and even in matters pertaining to the patient lessens and finally becomes non-existent. (8) Crowds seem to irritate the patient, and he prefers to remain by himself or with one or two close friends. It becomes (9) difficult for him to concentrate, and he gives up reading. (10) Decisions cannot be made. (11) Any innovation is dreaded and opposed.

Physically, his activity decreases to a minimum. Each movement requires great effort. Fatigue and a feeling of weakness is prevalent. The digestive process is impaired, and vague hypochondriacal pains and disturbances appear.

The speed of the thought processes is decelerated. It is an effort to think through a problem. Each problem is surrounded by marked emotion, fear of failure, and concern about dire consequences. Speech becomes slow and one central theme of concern is present.

This depressive state may not interfere with the routine life of the patient. He may continue in his business or job, being noticeably below his normal level of efficiency, but still able to perform his work. He withdraws from his friends, and frequently will visit one physician after another in an effort to find some physical basis for his difficulty. The depressive episode clears up gradually, and the patient recovers, returning to his "usual" level of psychophysical activity. The duration of such an episode varies from a few months to a few years.

THE ACUTE DEPRESSION

The acute depressive episode varies from the mild attack only in intensity. The patient feels intensely melancholic and hopeless. There seems no value left to anything in life. Efforts to convince him to the contrary will fail, even though the patient may actually have achieved much. He tends to depreciate all his own assets, and to overevaluate those of others. His mood becomes so depressed that suicidal thoughts will occupy his mind, and often there are actual suicidal attempts.

Physical activity is greatly depressed. The patient may sit about for hours doing nothing, staring into space, and crying. In the *agitated depressions* there may be restlessness, wringing of the hands, constant picking at the face or rubbing of the scalp. The patient looks prematurely old, and constipation often becomes extreme. The loss of weight is rapid, patients not infrequently losing thirty to forty pounds in a few months. Sleep seems lost altogether, despite the use of powerful sedatives.

The stream of thought is similarly retarded. The patient finds it difficult to make the simplest decision, and in extreme cases cannot decide what dress to wear, what shoe to put on first, etc. At the same time there is considerable worry over nonessential incidents, worry which never leads to a solution. The speech becomes slow and soft-toned. In the *depressive stupors*, speech may cease altogether, and the patient appears to be in a coma except for his open, unblinking eyes. In the agitated depressions there may be constant talking, of the whining, complaining variety.

In some of the agitated depressions there are feelings of guilt. The patient is sure that he has been the cause of the death of his father, or of illness in his family. He may feel that he has "committed the unpardonable sin." He develops delusions of poverty, of malignant illness, of impending disaster. Intense suicidal drives are found in these patients.

The *involutional melancholias* appear to be similar to the usual depressive attack. Although many medical authorities believe that the deficiency in ovarian hormone is the primary etiologic factor, this point is in dispute. In any event, most of these cases follow the same pattern as other depressions.

In the *neurotic depression* the patient's main complaints dwell upon physical ailments. Often these patients are diagnosed as being psychoneurotic, but further investigation will usually unearth an underlying manic-depressive depression.

The duration of the depressive episodes varies widely. The average case lasts from one to two years; but some cases have fleeting attacks once a month, and others have attacks which continue throughout the life of the patient. Each depressive attack has a spontaneous remission. Many of these episodes are followed by a manic attack, while in other instances there is a

period of normalcy after the attack, only to be succeeded by another depressive episode.

The treatment of the mild attacks is primarily through constant reassurance, work guidance, and socialization. The severer attacks usually need to be dealt with in a hospital because of the danger of suicide. Convulsive (electric) shock therapy is of great value in clearing up this type of illness. Psychotherapy, directed toward any associated psychoneurotic tendencies, is important.

SCHIZOPHRENIAS

The schizophrenias are a group of personality disorders, rooted in a constitutional predisposition, occurring most commonly after adolescence, mediated by a disturbance in affect and conation, and manifested by symptoms of withdrawal into fantasy, disturbed emotional control, altered function of association processes, and intensive use of projection mechanisms.

The present concept of schizophrenia has emerged by stages during the last century. In 1850, Morel used the term "démence précoce," although the condition he thus described was far more inclusive than the present equivalent. Kahlbaum (1863) used the term "vesania," which, though more definitive, was nevertheless vague in its outlines. Hecker (1871) described a condition of hebephrenia, and Kahlbaum (1874) culled out a mental state which he called catatonia. Kraepelin (1887) defined the symptom complex of dementia praecox which is in use today. Bleuler (1911), while concurring in this syndrome, objected to the term "dementia praecox" since many cases do not develop dementia, and many cases are not "precociter." He advocated the use of the term schizophrenia (Fr. *schiz*, split; and *phrenia*, mind).

ETIOLOGY

The etiology is unknown. Heredity appears to play some role. Koller and Diem advanced statistics indicating that a large percentage of schizophrenic patients have significant family histories; but they included as evidence of hereditary tainting such conditions as "psychoses," "nervous diseases," alcoholism, apoplexy, senile dementia, and "abnormal character." A large, though somewhat smaller, percentage of normal persons have similar factors in their background. Such statistics leave much to be

desired. Humm finds that 3 to 5 per cent of the siblings and of the parents have schizophrenia; but these figures must, in themselves, be regarded as an estimate, inasmuch as there are many minor schizophrenic reactions which never come to the attention of institutions or investigators. From rural districts, for example, there are about half as many patients admitted to hospitals for mental disease, in proportion to the population, as there are from urban centers. Adjustments to city life are more difficult, hence the greater number and intensity of precipitating factors; moreover, many personality disturbances which cause little conflict on a farm create marked disturbance in a city. Rosanoff, et al., in a study of identical twins, finds that 68 per cent have the schizophrenic illness in both siblings, whereas only 5 per cent of non-identical twins have the illness in both siblings. Rosanoff's studies would indicate that the inherited constitution is an extremely important though not the only factor. Ruxlin, on the basis of similar studies, states that schizophrenia is transmitted as a recessive character of the Mendelian type.

The physical constitution of these patients, according to Kretschmer and subsequent authors, is of an asthenic-athletic type. Dysplastic types also occur frequently. From an anatomico-physiological point of view, these patients tend to have a long, narrow heart which weighs less than that of the average patient of the same age, low blood pressure, low basal metabolic rates, and other evidences of physiologic sluggishness. These differences, however, are relatively within the normal range rather than abnormal. Pathologic studies do not reveal any characteristic organic defect.

Statistics show that this disease has the highest hospital admission rate of any single mental disease. In this connection it is interesting to note that whereas 19.6 per cent (1941) of all first admissions to the state hospitals are schizophrenics, 50 per cent of all patients who remain in state hospitals are schizophrenic. This discrepancy results from the fact that patients of other groups either recover or die, whereas the schizophrenic patient tends to live for many years in an institution. The peak age of admission of these patients to state institutions is in the middle twenties, but this fact again needs clarification. Many patients have symptoms for a long period of time before they are admitted

to an institution, and many other patients do not develop the illness in chronic form until the middle thirties. Marital status also seems to play a role; the incidence of this illness in the single, widowed, and divorced is much higher than in married persons.

The prepsychotic personality, in a large proportion of cases, presents, as Hoch pointed out, a characteristic pattern. From earliest childhood, these patients, while still not abnormal, are much more shy, much more sensitive than other children. Their feelings are easily wounded and they tend to brood. They are likely to daydream and read while other children are out playing. They are more asocial, desiring the company of others and yet feeling ill at ease and at a loss for words in the presence of others. Usually they are quiet, obedient, and "cause less trouble" than the average child. They seem lacking in energy, though they may excel scholastically. Many schizophrenic patients have been among the best of students; yet, when they enter competitive life after leaving school, they seem not to do so well as their less scholastically able companions. To the observer, these persons seem normal; within the patient there are marked feelings of inferiority, moralism, and excessive inhibitions.

Many normal persons who never develop any psychotic responses have similar backgrounds, so that such "introvert" personality traits are not pathognomonic of schizophrenia. Conversely, however, schizophrenic patients are rarely "extrovert."

The constitution of the patient, despite its significant characteristics of physique and temperament, is, in itself, usually insufficient to bring about a schizophrenic reaction. Rosanoff's studies of one hundred identical twins, in which 68 per cent of both identical twins suffered from schizophrenia, indicates that in the remaining 32 per cent there must have been a precipitating factor.

Various precipitating factors may occur, and the illness results from the interaction between these factors and the constitution. Where the constitution is extremely susceptible, ordinary events of life will often bring about an abnormal personality reaction; where there is relatively less predisposition, greater stress is necessary. The precipitating factors may be: (a) physiologic, (b) organogenic, or (c) psychologic.

The physiologic precipitators may occur with the physiologic changes that develop at puberty, at pregnancy, and with menopause. Only rarely do schizophrenic psychoses begin before adolescence, a fact indicating the presence of some powerful relationship to the psychobiologic changes during this period. Similarly, psychotic responses may occur after pregnancy and during the menopause.

The organogenetic precipitating factors include all toxic, infectious, degenerative, traumatic, and neoplastic states. With any one of these illnesses, a susceptible constitution may react with schizophrenic symptoms.

The psychologic stresses are multitudinous, the more disturbing ones being those of pride and ego wounding aspect rather than those involving material deprivation. A patient's feeling of being unwanted, of conflict over competition with a sibling for a parent's affection, of inferiority and inadequacy as compared with some ideal standard, of resentments over minor or imagined slights, and many other similar psychic "traumas" act as potent forces in accentuating the associability and the withdrawal from reality already present in the susceptible person.

In substance, therefore, the etiology of schizophrenia may be said to be the result of (a) susceptible, inherited constitution as modified by (b) physiologic changes (such as puberty) and as precipitated by (c) organogenic or psychogenic forces.

SYMPTOMS

The symptoms vary widely from that of the patient who deteriorates quickly and must be hospitalized early in the disease to that of the patient who has a slowly developing paranoid state but has enough balancing features to live for many years in society without requiring hospitalization. Most cases, however, follow a rather typical pattern.

The usual onset occurs after adolescence in a shy, sensitive, quiet person. The earliest signs are usually those of withdrawal. The patient, already aloof, mingles less and less with his friends, and spends more and more time alone, reading or daydreaming. Daily events no longer seem to interest him; and situations in the business, scholastic, social, or political worlds, which ordinarily arouse comment and reaction, are ignored or given only the slightest of

response. During all this time he appears normal—"but quiet." He becomes preoccupied, sitting for hours without moving. Often he does not read or understand the book which he holds before him. He seems deep in thought, yet, when questioned as to what he was thinking of, replies, "Nothing." His thoughts are vague, unspecific, wandering. He seems unhappy, dissatisfied, depressed and does not relish any of the entertainment in which he formerly indulged. He may develop an abnormal interest in philosophy or psychology, feeling that he is "going crazy" and seeking some means of help. He may have waking dreams about sex, yet avoid the company of women and indulge in excessive masturbation. Occasionally he develops a religious fanaticism, often even despite a background of indifference to religion. He becomes sensitive to an extreme, and his pride is wounded by imagined slights or the unthinking actions of his friends. His conversation becomes erratic, and often he is evasive, circumlocutious, insinuating that something is wrong without committing himself. Ideas of reference develop; and the smile of the passerby, the conversation of two strangers, the joking story of a friend, all have special and usually sinister meaning and significance to the patient.

Gradually his work habits deteriorate. He becomes less efficient and makes thoughtless mistakes. Eventually he leaves his job or is discharged because of his preoccupation and queerness. His habits deteriorate so that he no longer presents a neat appearance, his clothes becoming unkempt, the underclothes often being unchanged and odorous, the face unshaven, the hair uncombed. Such deterioration is especially noticeable in women patients. The patient becomes suspicious of his acquaintances, and imagines that they dislike him. A misplaced tool at his workbench, a missing eraser from the typing desk, a smudge of ink on the study book, all indicate that someone deliberately was irritating him. Gradually the feeling of being irritated develops into a "persecution complex," and his acquaintances seem to be organized into a "gang" whose sole function is "to get him." At first the patient has no clear idea of why he should be so persecuted, but after a period of time his rationalization processes develop a reason and a plot.

The patient begins to laugh and talk to himself, smiling, grimacing, or making gestures to

himself. His former affection for his parents or family suddenly turns to rage and intense dislike—alternating at times with overwhelming demonstration of love. He has difficulty in sleeping, staying awake far into the night and lying in bed till late in the morning. His appetite is altered, and he may not eat for days at a time, or, suddenly, wolf down several meals in one. His words and actions no longer seem appropriate to the situation.

The whole process may take years to develop, or may be precipitated by a pregnancy, a surgical operation, an acute illness, etc. The patient will appear to be acutely fearful, rambling incoherently about plots and dangers. He may see figures peering at him through the windows, men following him on the street, and hear noises which are sounds of danger. His excitement may become extreme. He may begin to run about the house shouting, talking rapidly and senselessly, destroying furniture, dishes, and all objects which come to his attention. The food may seem poisoned to him, and his family may appear to be in a plot to kill him. Delusions and hallucinations of all sorts develop. He may become exhibitionistic, or may masturbate in public. He may make crude sex proposals to strangers, or insist that "voices" accuse him of "awful" sexual thoughts. His reaction usually becomes so intense that he needs to be sent to a hospital.

In the hospital the acute symptoms usually subside after a period of time, lasting from several hours to several months. There are many variations in the clinical picture. One patient may become mute, refusing to speak, lying unmoving for hours, staring into space, and not attending to the eliminatory functions. Others will elaborate on their delusional story, weaving complex plots and suffering from vivid hallucinations. The appetite becomes capricious and the patient may need to be tube fed to prevent starvation. Sleep is poor, and sedatives may be necessary. Restraints may be required should the patient attack other patients in the ward. In the later stages there may develop peculiar repetitive mannerisms (stereotypes), all statements heard may be repeated (echolalia), or all actions mimicked (echopraxia). Negativism may be extreme, the patient not only not cooperating but doing the opposite of what is asked. There may be alternating periods of stupor and excitement.

In institutions most patients reach a level at which the disease is arrested. These patients retain their delusions and mental aberrations but can be utilized in farm work, laundry work, and in all the household duties of an institution. In schizophrenic patients the major cause of death is tuberculosis, and almost half of these patients live in the state hospitals for more than twenty years before death. Many patients can be paroled from the institution to return to their homes; and, even though they are not cured, they may be able to adapt themselves on a lower social level. However, large numbers of them need to be readmitted to the institution as a result of recurrence of symptoms.

SUBDIVISIONS OF SCHIZOPHRENIA

According to the standard classification, there are four subdivisions of schizophrenia. These subgroups are, however, extremely vague in their outlines, and are difficult to distinguish except for the relatively "pure" case.

The *Simple Schizophrenic* person is often unrecognized as suffering from a mental illness. He is usually withdrawn to an extreme but still capable of social existence on an inferior level. There is practically no interest in the outside world either in terms of the social situation or even of the opposite sex. Many of these patients, despite extremely high intellectual abilities, wander about the country working as laborers, dishwashers in restaurants, waiters, etc.; and their period of employment at any one time is short-lived. Much of their time is spent in daydreaming, and mild delusions are present. They are usually considered as "queer" but rarely come into conflict with society except when arrested as "vagrants."

Hebephrenic Schizophrenia (hebe, puberty) occurs most frequently after puberty and adolescence. This form is the most acute and the most rapidly deteriorating one of the schizophrenic reactions, and presumably has the greatest amount of constitutional predisposition. The symptoms are silly, childish behavior, extreme impulsiveness, violent unexplained laughter, intense but rapidly changing and unsystematized delusions, vivid hallucinations, fragmentary utterances, and early loss of control over bowel and bladder. Complete dilapidation and early death is common.

Catatonic Schizophrenia (cata, decreased;

tonus, tone) is characterized by disturbances in motor control, in variation from depressed to excited states, and in stupor. During their illness, these patients are extremely quiet, often completely mute, and refuse to eat. They also exhibit marked negativism, and are indifferent to painful stimuli. A motility disorder called *cerea flexibilitas* (waxy flexibility) occurs, so that their arms or other muscles can be placed in the most distorted of positions (as one could in a stiff-jointed manikin) and will be maintained in those abnormal positions for hours at a time. These patients may have temporary periods of frenzy and rage, which usually subside quickly, to be followed by extremely long periods of immobility.

Paranoid Schizophrenia (*para*, twisted; *noia*, thinking) is characterized primarily by "ideas of persecution." Most paranoid reactions occur later in life, indicating less of a constitutional predisposition than in the hebephrenias, and usually with greater disturbance resulting from psychogenic factors. Many paranoid schizophrenic patients live for years in a community, keeping their delusions to themselves and having sufficient balancing personality factors to earn a livelihood or to adjust on an inferior social level. Initially there is marked vagueness in thought and action, followed by vague feelings of persecution. These patients often have more energy than other types of schizophrenic patients and may maintain a fairly high work output while their delusions are developing. The delusions are at first fragmentary; but, as the patient begins to rationalize and justify them, they become woven into a complete pattern—into systematized delusions. Eventually these patients either express their delusions and hallucinations or commit some violent act as dictated by these ideational or sense falsifications, and are committed to an institution. Paranoid patients usually live to an older age in mental hospitals than do other schizophrenic patients.

A condition of true paranoia has been described. This condition presumably differs from schizophrenia because of the absence of hallucinations or incoherence of thought, and the retention of interest and efficiency in social situations. It is more likely, however, that these states represent one of the forms of paranoid schizophrenia, in which deteriorating symptoms appear late in the illness because the con-

stitution is least involved and psychogenic factors most potent.

SCHIZOPHRENIC PSYCHOLOGY

Within the framework of the constitutional predisposition can be seen a definite pattern of psychologic mechanisms.

In the prepsychotic state, as has already been mentioned, most patients show a disturbance in affect. For the most part, this affect is seen in "sensitivity" and in "easily hurt feelings." These patients, in childhood, experience emotional disturbances even more keenly than the ordinary child, though their reactions to such emotion is one of inhibition rather than of expression. They are more than usually fearful of meeting strangers, of new situations, and of criticism. They feel insecure and in need of constant reassurance and moral support. They tend to over-react to irritations and slights; and, instead of forgetting shortly, as is the tendency of their more extrovert companions, they brood and elaborate upon their hurts. Their emotional responses are either inhibited, resulting in brooding quietness and "imaginativeness," or, if expressed, are excessive, violent, out of proportion to the stimulus, and highly symbolic.

This emotional sensitivity leads in the prepsychotic state to withdrawal from possible hurts and to shyness. Actions which may give rise to criticism are avoided, so that the patient is a "good" child and obedient. For the same reason, later in life there is an excessive moralism extending to any desire which is socially taboo. Since desires are ever-present, there arise conflicts and feelings of guilt, even in children—guilt at the thought of having a socially taboo desire. Most of the thinking becomes subjective, related entirely to their own feelings; and there is relative disinterest in the world about them, in other playmates, in games. These reactions involve "affect," differing from the usual emotional reaction in their method of expression, and are present in the pre-psychotic state.

When the schizophrenic psychosis occurs, precipitated by some physiological, organic, or psychologic stress, the psychology of the patient is manifested by: (1) withdrawal into fantasy, (2) marked disturbance in emotional control, (3) altered function of the associative processes, and (4) intensive use of psychologic mechanisms.

WITHDRAWAL INTO FANTASY

In the illness the shyness of the prepsychotic state becomes extreme. Reality is more than ever too painful to face directly, and daily events too irritating. The patient withdraws from his contacts and from reality and spends more of his time in reverie or fantasy. External events penetrate less and less into consciousness. The thoughts, unchecked by reality, deal with vague wishes, fears, repressions, and emotional experiences; the resultant verbal and motor responses of the patient are disconnected, vague, and bizarre.

In fantasy the association processes have "free flow," unchecked by objective comparison or even by conscious control; and the associations become guided purely by emotional relationships. When there is primary emotional concern, the fantasies (associations) will revolve about this central theme, but the thoughts about such a central idea will still be amorphous and dreamlike. At first the fantasies are pleasant and "wish fulfilling"; but the inhibitions and repressions, operating even within daydreams, soon give rise to frightening and emotionally painful fantasies. The guilt feelings which arise, and the resultant wishes and fears, desires and repressions are then expressed in symbolic fashion.

The patient is completely concerned with himself—subjectivity is all-inclusive. Egocentricity is the basis of his thought. Even the external events which do penetrate to his consciousness have a special meaning for him (ideas of reference). The greater the withdrawal into fantasy, the less the corrective effects of reality. A vicious cycle is thus created, and the habit of living in fantasy becomes more and more fixed.

Despite all this withdrawal and lack of contact with reality, the patient's sensorium remains clear. When the patient can be stimulated to pay attention and respond, his orientation, memory, ability to calculate, etc., will be shown to be normal, even though he is otherwise deteriorated. This condition is in sharp contrast to the thinking changes of the organic psychoses wherein the sensorium is disturbed but contact with reality is maintained.

DISTURBED EMOTIONAL CONTROL

Conscious control over the emotions is minimized or lost. The patient feels keenly dis-

turbed, yet "automatically" inhibits the expression of his feelings. He becomes apathetic and unresponsive to situations which are emotion-producing in the "normal" person. This lack of emotional response is the result not only of inhibition, but also of the intense subjectivity of his disinterest in the difficulties which affect others. Little, if any, attention is paid to these external affective conditions unless in some way they strike a receptive chord in the patient's subjective evaluation. Moreover, by means of this emotional withdrawal, the patient builds a protective wall about his sensitized ego.

Despite such attempts at protection of the self against painful emotions, disturbances continue to occur within the patient's stream of mental activity. The free flow of associations, unchecked by reality, guided solely by emotional associations and pain-pleasure conflicts, results in an elaboration of the emotional tones. Minor irritations, long dwelt upon, become intense hates; mild feelings of inferiority become intense guilt reactions. The emotional tension within the patient mounts; it may be completely inhibited by withdrawal into a state of stupor, or it may be expressed symbolically or in a violent outburst of emotion. The associative processes become so overcharged with affect as often to result in immediate expression—as impulsive acts. Minor irritations, unchecked by normal control, produce violent attacks upon the offending person. Lifelong normal affections may thus be overruled in a moment's disaffection.

The emotions thus developed may be displaced and discharged upon some incidental irritation. A trivial act, of no apparent relation to the patient, may serve as a focus upon which to vent the stored-up tensions. The guilt feelings become intense; the patient attempts to relieve his ego of the emotional pain by projecting the cause of the guilt, blaming others (delusions) for the series of events which resulted in his state. He projects the guilt feelings into the sensory field (hallucinations), audibly hearing the accusations made by "someone else."

The catatonic patient, for the most part, inhibits his emotional tensions, and is thus frequently found in the state of mutism, negativism and stupor. The paranoid patient for the most part, attempts to deny his responsibility for the intensified guilt conflicts, and, projecting

them, develops systematized delusions. However, no sharp line of distinction can be drawn between these two groups, for all these processes occur in all the forms of schizophrenia.

ALTERATION IN THE ASSOCIATIVE PROCESSES OF THOUGHT

It is the disturbance in associations which render the verbal and physical responses of the schizophrenic patient "queer." On the basis of the constitutional predisposition, the disturbance in affect (i.e., the hyper-sensitivity) results in marked subjectivity (egocentricity) and marked inhibition. The association processes, over-concerned with the self and losing contact with reality by withdrawal into fantasy, become dominated by feeling tones rather than by "logical" or experimental facts.

There results: (1) A dissolution of many acquired patterns of association, so that the patient not only does not carry out his usual social responses, but changes his accustomed manner of dressing, become sloppy in his appearance, "forgets" his ordinary table manners, and his methods of eating. His associative processes no longer follow the direction of previous training.

(2) The associative processes become fluid and do not adhere to the more rigid regulations of experience and of reality. The emotional tones of each association bring about other associations with similar emotional tones, and the associations flow in many directions without "reason" or common "understandability." This fluid, "unrational" flow of associations is seen in the following verbatim statement. The patient¹ who was admitted to the hospital in a state of acute excitement, improved somewhat under shock therapy, and, on request, gave the following explanation of her previous actions: "A gray-haired woman taunts me about my glasses." (Actually, this woman had just walked into her room and had said nothing.) "They've taken mine away. So I snatch hers. They're rimless. I twist the nose-piece till it breaks, hurl the now-separate lenses to the floor. I think about having to wear those glasses. I despise them so. Then the idea flashes. It's my right eye that is more nearsighted. It offends me. The Bible says to pluck it out. I try, but the muscles are stubborn. I whimper at this frustration. The

¹ Case history through the courtesy of Dr. J. O. Freund.

nurse hears me. My finger nails are cut short while I kick and spit at them. How dare they? She tells me to behave myself, to act like a lady. I relax, but gaze up piteously while the inexorable snip-snipping goes on. How tender my finger tips are. I stare at my nails. The deep color of the polish disgusts me." (The patient had to be restrained because of the attempt at self-enucleation of the eye.) This flow of associations indicates how changeable is the direction of the flow and how impulsive action follows incidental associations.

(3) There is an intensification of the emotional tone of the associations so that minor incidents assume intense affect. The "thought" of the above patient that the eye "offends me" is sufficiently disturbing to result in an abnormal response. Stimuli which "penetrate" through to the patient result in overwhelming and out-of-proportion reactions. Violence may occur apparently without cause, but on further examination one finds that the stimulus for the action had long existed. Thus, one patient "had a pet cat for five years. It was cute, and I played with it a lot. It scratched me. I didn't do anything right then, but I thought about it, and then took it out and killed it." The expression of such emotional intensifications is, however, inhibited in most patients, and comes to the surface at infrequent intervals.

(4) There is a loss of ability to direct the flow of associations. These patients are unable to "think through" to a conclusion because of the fluidity of their associations. Subjectively, they complain of an inability to concentrate and of their "thoughts wandering." Objectively, they seem preoccupied with a problem, but in the advanced stages there is no ability to "reason out" the problem. In the early stages of the illness, the patients are often able to give correct solutions to a question, provided the span of attention required is not too long; but the flow of associations is so controlled by the emotional patterns, that "logical thought," with consideration of experiential factors, is difficult, if not impossible.

(5) There is, however, a grouping of associations around emotionally intense concerns. Desires, fears, conflicts, all serve as centers towards which, and from which, the emotionally toned associations flow. When subjected to psychologic mechanisms, these "emotional centers" form the basis of delusions and hallucinations.

In the deteriorated schizophrenic patient, who has lost all contact with reality, these delusions are fragmentary and unrelated; in the slower developing illnesses, wherein more contact with reality is maintained, as in the paranoid patient, the delusions are woven into a unified pattern.

INTENSIVE USE OF PSYCHOLOGIC DYNAMISMS

The various "unconscious" mechanisms utilized by the personality in the normal or in the prepsychotic state to protect itself against the wounding of the ego are even more intensively practiced in the schizophrenic state. Particular use is made of the mechanisms of repression, rationalization, symbolization, projection, and systematization. Such psychologic measures are utilized by neurotic persons and by "normals," the difference from the schizophrenic patient lying in the "reality testing." The normal or neurotic person modifies the use of these mechanisms in varying degrees, in conformity with the total gestalt of the personality, the problem, and the prevailing environment. The schizophrenic patient, being withdrawn, does not have the modifying influence of reality on the already unhealthy psychologic mechanisms; and the resultant psychologic responses are "queer," bizarre, and un-real. The patient represses and inhibits his emotions more intensely than the neurotic patient, and expresses his conflicts in the exaggerated symbolism of delusions, mannerisms, stereotypes. His ego, extremely sensitive in the prepsychotic personality, is even more sensitive in the illness, and the guilt feelings are rationalized into acceptable "others-being-responsible" causes (delusions). The projection mechanism is strongly operative in the delusions and hallucinations.

The use of these various mechanisms is further complicated by the distortion of the associative process; and the greater the fluidity and lack of goal direction of the associations, the more bizarre and incomprehensible the results of the symbolization, projection, etc. The deteriorated patient instead of expressing clearly defined delusions, definite mannerisms, etc., speaks only a "gibberish" or "word salad" and moves in aimless, incoherent fashion.

The content of the delusions utilizes the knowledge of the patient and the general concepts of the day. Thus, in the Middle Ages, the

delusions of the schizophrenic patient were centered about witches and devils who tempted and taunted the patient. Werewolves and mystic incantations played an important role in the patient's explanations (rationalizations and symbols) of his emotional unrest. In this century, the patient's delusions center about radio waves, on electricity influencing the mind, on dictaphones recording one's thoughts, and with television spying upon him. The form of the delusions is thus of little diagnostic value.

PROGNOSIS

Once the illness has developed, the prognosis in schizophrenia is relatively poor. The rate per thousand schizophrenic patients discharged as recovered is 7.3, in contrast to the rate of 142.8 for manic-depressive psychoses (*Annual Statistical Review, 1940, State of Illinois, p. 58*). The number of schizophrenic patients remaining in mental institutions is almost half the total population of the institution. Frequently, the patients improve sufficiently to be returned home, on parole, and many are able to live on an inferior social level particularly on a farm or in a rural district. However, many patients break down and need readmission to the hospital. In the hospital, many patients are able to assist in the "household duties" and perform fairly well although their work is often interrupted by acute psychotic episodes. A common cause of death for these patients is tuberculosis, and the median age of death is 56.2 years (median age at admission being 30.2) (1940, Illinois, *ibid*).

Since the advent of the shock therapies, the prognosis for early cases has greatly improved. If the patients are treated early in the disease; i.e., within six months of the onset of the acute symptoms, the percentage of recoveries is high. The statistics for such recoveries are still unreliable, the originators of the shock therapy claiming that more than 75 per cent of the cases recover under their therapies, but further experience indicating that the rates are much less. Treatments given after the patient has been ill for several years seem to have little curative effect. However, even markedly deteriorated patients apparently benefit from such therapy in that they are better able to take care of themselves, and are able to cooperate more effectively in minor routine duties.

TREATMENT

Until 1935 the treatment of schizophrenia varied with each physician. Almost every conceivable method of therapy was used. Psychologic therapy, removal of possible sources of infection, colonic irrigations, fever treatments, prolonged sleep treatments, etc., were all tried; and though each seemed to have some measure of success, they failed in the hands of most investigators. In the 1930's, Sakel of Vienna suggested the use of prolonged insulin comas in the treatment of the schizophrenic patient. About the same time, Meduna of Budapest suggested the use of convulsive shock therapy. Both of these therapies have come into wide use, despite much initial opposition.

The present consensus is that these physical treatments are of the greatest value in schizophrenia. The convulsive shock therapy is relatively less effective in schizophrenia than are the insulin comas. Initially, Meduna used metrazol as the convulsive agent. A host of these agents have been tried; and at the current writing, the induction of convulsions by electric shock is the method of choice. It seems to matter little in terms of results how the convulsion is produced. The number of convulsions given varies from ten to forty and as a rule are given every other day. There are, however, many individual variations in this treatment.

The insulin coma treatment consists, in essence, of giving the patient large doses of insulin early in the morning and withholding food for four hours. The dosage of insulin is increased daily until coma results. Comas are usually permitted to last one to two hours, after which the patient is revived by food given via stomach tube or by glucose intravenously. Usually, the average patient is given from fifteen to fifty insulin comas as a course of treatment.

An essential element in treatment in addition to these shock methods is psychotherapy. There are at least six principles in this psychotherapy. (1) Constant encouragement and reassurance, (2) extremely gradual effort in persuading the patient to face reality, (3) avoidance of trying to convince the patient that his delusions are fallacious, (4) explanation of symptoms on a physiologic or psychologic basis, (5) therapeutic discussions about emotional conflicts, avoiding

initially too specific an approach to the patient's problem, and (6) socialization and work therapy. Under the combination of shock treatments and psychotherapy of this sort many patients in the early stages of the illness seem to recover completely and remain well.

Later, a surgical technique has been developed in the treatment of psychotic patients. Certain areas of the frontal lobe of the brain are separated surgically (prefrontal lobotomy) from the rest of the brain. Some of the cases so operated on seem to have had excellent results, but final conclusions cannot yet be drawn.

PSYCHOSEXUAL FUNCTION IN WOMEN.—*Introduction:* The psychosexual development of each individual—men and women alike—is a complex process: it is the evolution of an innate anlage (constitution) under the influence of the environment. Environment in itself is an intricate interplay of culture and its effects on the individuals who represent the immediate environment of the child. Since the immediate environment usually is created by the parents, the genetic and the environmental factors become so closely interwoven that only a detailed analysis of all factors will reveal which elements of the emotional development of an individual are determined by genetic factors and which are the results of environmental influences. The interplay between biological and environmental factors represents the field of investigation of the dynamic psychology, which offers the concepts upon which we will elaborate in our discussion of the developmental process of the women as it unfolds in our culture within the family.

PSYCHOSEXUAL DEVELOPMENT

According to the concepts of psychoanalysis, the sexual drive is a manifestation of energy originating in the process of growth and it results from integration of various tendencies which spring from the needs of the growing individual. The earliest phase of this development is determined by the relationship between mother and infant. The woman's emotional satisfaction in being a mother, her instinctive readiness to nurse, to feed, to take care of the baby, not only satisfies the infant's physiological needs but also provides it with pleasurable sensations. Out of the gratification of the receptive needs develops the infant's first emotional attitude * the confident expectation that the mother will satisfy all needs. This has the same importance in the psychosexual development of the infants of both sexes; boys and girls alike become deeply disturbed in their emotional life if such confidence cannot develop. If, as it normally occurs, the early relationship to the mother is undisturbed, the mother becomes the first teacher of the infants of both sexes. Under the sheltering security of routinely returning gratification the infant is led by the mother gradually to new activities. Through her the infant discovers the first objects of its surroundings and learns to walk, to talk, and to control its sphincters. Together with this self-assertion begins to play a role in the emotional manifestations of the infant. In this phase of development, which occurs in the last quarter of the first year and/or in the beginning of the second year, one may already observe definite differences in the behavior of the sexes which are motivated by specific emotional needs. These, in turn, are caused by the difference in the anlage. Although similarly important for the normal development of both sexes, the emotional security which results from the undisturbed confidence in the mother affects the infants of both sexes differently. It gives the boy permission for self-assertion and a sense of courage in using his growing muscular power; thus he may free himself from his dependence on the mother in order to start a development in which identification with the father becomes the leading motive. The girl's development

takes a different course: the sense of security with the mother gives her the first and most effective impulse for identification with her. As long as the girl's relationship with the mother remains undisturbed, i.e., unambivalent, she will easily imitate the mother, follow her advice and learn from her without conflict. As an example of the behavior manifestation of differences in developmental tendencies we may cite the fact, quite well known to mothers, that the toilet-training of boys is usually a much harder job than the training for habit-formation of girls. This seems to indicate that girls learn from the mother by identification willingly while boys learn if and after their need for self-assertion was satisfied too. Several behavior manifestations, which are decidedly feminine, may be noted already in the two year old or even younger girl: her walk, her talk, her interests, her activities are different from those of the boys. The little woman can be recognized in the infant especially by the gestures with which she approaches persons of her environment or responds to them. For example, the girl overcomes her shyness usually with some touch of flirtation, the boy with some self-assertion.

Even more significant for the development of the psychosexual function are those manifestations which show the child's libidinal interests in its own body. In this respect the dissimilarity in behavior is easily recognizable and, according to psychoanalytic concept, is directly related to anatomical sex differences. The little boy, aware of the organ which produces pleasure, concentrates upon his genitals for gratification;¹ the little girl's interest in her body remains diffuse and is mostly expressed as generalized pleasurable sensations and curiosity in herself. The little girl's great pleasure in looking in the mirror, for example, is not only imitative. There was, and still is, much discussion in the psychoanalytic literature about the primary sexual development of the woman. Freud's thesis is² that the girl's genitals, except for the clitoris, remain completely undiscovered and without

sensations until puberty, and that, therefore, her first sexual response is that of curiosity regarding the genitals of the other sex and of making comparisons with her own; the resulting feeling of inferiority nourishes in her a steady envy of the penis. Other investigators assume that the evolution of the feminine sexual anlage arouses the girl's interest and curiosity in the other sex. *There are many observations recorded showing that little girls of well adjusted parents do not seem to show sexual curiosity regarding their brothers or playmates nor regarding their fathers until after they have achieved a special developmental age, usually that of three to four years. Experiences may determine the developmental course in this respect; observations of others or sensations in her own body may steer the attention of the little girl in one or the other direction. Any conflict which may arise between mother and daughter at this early age threatens the girl with the loss of her mother's love. Thus the girl gives up many of her primary desires to save herself the security of the dependence on the mother.*³ Although this may delay her development, at the same time it gives her opportunity for the process of identification with the mother which finally leads to the next developmental phase, in which the girl becomes able to give up the mother as the exclusive object of gratification and turns to the father for gratification of her libidinous desires.

One of the earliest observations of psychoanalysis is that the psychosexual development of every individual reaches its most important juncture at this intensification of the emotional attitude toward the parent of the opposite sex—this is referred to as the Oedipus complex. When the girl turns to her father for gratification, she comes into conflict with her mother, the source of gratification of her dependent needs. Thus, at the oedipal phase of the development we meet for the first time the conflicting tendencies of wanting to be the child—to be loved by the mother—and the desire to be in her place and to be loved by the father. The competition with a not well adjusted mother may carry with it guilt and the fear of punishment; this may be accepted by the girl as a stop-signal; she turns back in her development

to remain the infantile person safe in her dependence. The normal evolution of the oedipal phase causes few disturbing manifestations. The children appear free in expressing their curiosity, their demands; the almost insatiable pleasure in quizzing the parent is a manifestation of the tendency to master these emotional needs. Children whose confidence in their parents has been shattered behave differently; they may become shy and ashamed of their body; they may masturbate compulsively without relief; anxiety attacks, nightmares, and other symptoms may disturb the child until she is able to conquer the onrushing and conflicting emotions.

This is the time when the girl's awakened curiosity leads her to the discovery that her body is different from that of the boys; she detects the penis. This discovery, as well as the more or less obviously preoccupation with it, is the expression of her own heterosexual tendency. The manifestations of the heterosexual tendency in a child are quite different from the mature adult expression of heterosexuality. Physiologically and emotionally the child is not ready yet for love and desire; instead, fear of the penis, of being hurt, of being damaged, are the infantile manifestations of the awakening awareness of the other sex. If this fear is connected with guilt, it becomes the most important motivation for the girl's intense desire to be a boy, i.e., to want to possess the penis. This appears to the girl as the solution of all conflicts; were she a boy she would not be afraid of losing the mother's love, and she would not need to accept a sexual function in which satisfaction is connected with danger of suffering. Some girls may become quite obsessed with the desire of identification with the boy; they may become aggressive toward boys, others are satisfied just by imitating them. The fear of the feminine sexual role appears even more threatening to the little girl if the birth of a sibling occurs about the time of the oedipal development. If this situation arises, identification with the mother undergoes a severe test. At such a time the girl's identification with the mother has usually developed so far that she may fantasize having a baby of her own. The changed appearance of the mother, however, makes the girl realize that to be like the mother means changes of the body. The dangers of giving birth may become a source of worry and fear if the child actually did observe birth; even

³ Brunswick, R. M., "The Pre-Oedipal Phase of the Libido Development, *Psychoanalytic Quarterly*, 9, 293, 1940.

more, it may result in severe anxiety if the child's hostile impulses toward the mother and toward the oncoming sibling caused guilty feelings. Thus, the fear of pregnancy might become an important factor in interrupting the process of identification with the mother. If this conflict is sustained into adult age it becomes the most important inhibiting factor of sexual function as we see in cases of frigidity and sterility.

The developmental phase of the oedipus conflict implies a degree of psychosexual growth in which the two psychodynamic tendencies which motivate the sexual function in women—the heterosexual tendency and the passive-receptive tendency—become manifest for the first time. These tendencies directed toward the object world of the child—the heterosexual tendency toward the father, the passive-receptive tendency toward the mother—are antagonistic, and thus create a conflict. The same psychodynamic tendencies motivate the psychosexual behavior also during sexual maturity, when, as we shall see, hormonal regulation coordinates those tendencies into unified emotional behavior.

After the turbulent oedipal phase is mastered the *latency period* follows during which the mental and sexual growth dominates behavior while sexual behavior itself recedes in the background. Yet the plays, fantasies, and also the characteristic behavior manifestations of the child indicate to the observer what direction the psychosexual development had taken during the pre-latency period. In some girls the increasing dependence, attachment to the mother, is the unconsciously chosen defense against sexuality; in others the aggressive tomboyish attitude indicates a flight from femininity. Both of these main groups of character formations can be considered a normal variation of feminine development. They may be overcome in due time or may become the source of severe disturbance, depending mainly upon the girl's basic pre-oedipal relationship to her mother.

Universal is the girl's inclination to play with dolls. This activity gives the child opportunity to master by repetition her most important conflicts and to express her most dominant interests. Her motherly attitude toward the doll may express her own dependence on her mother: "I love my doll as I want to be loved by my mother." A hostile attitude toward the doll

might express the girl's hostility toward her sibling and/or toward her mother. It reveals, however, a more important conflict if it expresses a sense of insecurity in her mother's love and its meaning is: "I hate my doll and punish her as my mother hates and punishes me." Such play-acting may be a response to a superficial frustration or it may express a deep conflict which often can not be mastered either by repetition in play or by aggressive behavior. An unloved child feels unlovable; she often hates herself even more than she can afford to hate her mother and, as a result, we observe more or less severe forms of depression even in the latency period. Moodiness and crying, the lack of capacity to play are manifestations of depression in childhood although they are rarely recognized as such. It is important to note that depression in children often takes the form of psychosomatic disorder: overeating—*bulimia*—or lack of appetite—*anorexia nervosa*—are severe manifestations of the child's self destructive impulses and, at the same time, they represent aggression toward the mother. Somewhat less serious but belonging in the same category, are the nausea and vomiting which often occur in the morning; these symptoms usually serve to keep the child home from school, thus they afford gratification also for the dependent needs. Among other psychosomatic symptoms which occur in this age we may mention enuresis, asthma and skin-conditions. However, we emphasize particularly those in which eating—oral conflict—plays a role since they appear more important here not only because they reflect the primary role of the mother conflict, but also because conditions such as *anorexia nervosa* and *bulimia* obviously interfere with the further sexual development.

The end of the latency period is the developmental phase which H. Deutsch⁴ in her recent book described as *prepuberty*. It seems that this period represents a last stand, a last defense against the femininity which, however, will slowly win ground as the physiological process of maturation proceeds. This phase—from prepuberty to complete maturation—may take many years since there are often remissions in the physiological and emotional growth. These account for many a charming characteristic of this age and do not indicate necessarily

⁴H. Deutsch, *Psychology of Women*, Vol. 1, Grunc and Stratton, New York, 1944.

serious disturbances in those girls whose previous development was normal. In the early puberty it becomes obvious that the fate of the oedipus complex determines the further psychosexual development. Although the psychodynamic tendencies which form the oedipal conflict might have been dormant during the latency period, they are awakened early in puberty by the incipient hormonal function. The newly stimulated interest in the father is quickly overcome by the normal girl and her interest in the other sex is soon tried out in various attempts of approachment outside of the family. It is different in the neurotic girl; in her the heterosexual interest is accompanied by much fear of and hostility toward the mother. The threatening conflict with her mother increases the girl's desire to suppress her sexuality, thus it may arrest her further development causing various neurotic conditions. The psychosomatic symptoms of puberty, if they are not repetitions of the orally determined neurosis mentioned above, usually show a greater involvement of the heterosexual component: thus anxiety, phobic symptoms, vasomotor neurosis (blushing), menstrual disturbances are the symptoms which prevail during this period.

However, except in extreme cases, the physiological growth proceeds. The greater the girl's desire to fight its manifestations, the more sensitive she becomes to every change within herself. Although the responses have endless variations, they might be grouped around two basic factors: (1) With the developing hormonal function heterosexuality becomes an emotional reality for the girl. While she might have been vaguely afraid of men before, now she becomes afraid of her own desires and tries to suppress them. Defense against the heterosexual aspect of sexuality represents one group of the emotional manifestations of puberty. (2) The growing sexual function produces hormones which libidinizes the body; this the girl rarely can enjoy without shyness and embarrassment, emotions which she has to overcome in order to accept femininity, her body, and her genital functions in a positive fashion. While the girl fears heterosexuality and doubts her own capacity to attract men, her emotional needs find expression in enthusiastic admiration for women. In the identification with the idealized woman her fantasy allows her vicarious gratifi-

cations of beauty and love, and prepares her step by step for her later sexual role.

MENSTRUATION AND PUBERTY

Menarche—the first menstruation—may occur at any time during the period from pre-puberty until adolescence. It is usually understood to be the sign of sexual maturity. Although this is not necessarily the case, the onset of the menstrual flow takes the central place among all events of puberty. The emotional reaction to it is usually quite marked. It is as if menarche were a puberty-rite cast upon women by nature itself; in all cultures it has been considered an exceptional condition. There is valid evidence to show that we look upon menstruation as the cornerstone of female development where sociological and physiological factors meet, marking the point at which adaptation to female sexual function may succeed or fail.

Anthropological studies of menstruation have dealt mainly with society's responses to and defense against the menstruating woman and they have shown that society—probably indicating man's society—is deeply afraid of the menstruating woman. It has often been demonstrated in the great variety of taboos and customs, that this fear on the part of society, whatever its unconscious motivation might have been, did necessarily influence the woman who menstruates, the girl who expects to menstruate. In primitive societies the girl has learned from her mother indirectly and by observation, that she will be excluded from society and that perhaps she will be regarded as a dangerous witch and this expectation certainly cannot remain without effect on the psychology of women. Although in our culture the taboo of menstruation is greatly decreased, menstruation is still surrounded with great secretiveness, which indicates the traces of taboos and superstitions of previous cultures. Besides the sociologically determined emotional factors there are also physiological motivations for the fear of menstruation. Menstruation is often painful; the fear of pain is deeply ingrained in physiology. The sight of blood might arouse not only the fear of pain but also it might stir up unconscious anxieties of mutilation, sickness, or even death. It was one of the early psychoanalytic observations that women connect menstruation with the idea of mutilation in their

fantasies and dreams; they dream about bloody acts which they commit or which are committed on them. This type of anxiety dream seems to confirm the psychoanalytic concept that for women menstruation means the loss of penis, and thus appears to be a satisfactory explanation for the fact that the first menstruation is usually experienced as a trauma.

The emotional difficulties characteristic of puberty, however, neither represent nor are caused by emotional reactions to menstruation alone. Individuals whose menarche came late, at the age of 14-17 years, may have emotional difficulties characteristic of puberty long before menarche; others whose menses began early do not show these emotional manifestations immediately; even though they may have reacted to the menstruation with aversion and distaste, their emotional puberty develops only later. The previous psychosexual development determines the emotional response to menstruation just as it affects the other manifestations of the unfolding puberty. If the previous psychosexual development had been burdened with anxiety and guilt feelings, the developing sexual desires may exacerbate anxiety and the defense against sexuality may grow. This defense may be expressed as a desire not to be like the mother. One of the most frequent symptoms of adolescent behavior is the girl's hostility toward the mother. It is she whom the girl blames for all the difficulties of her adjustment to the sexual role. We pointed out previously that the mother's personality, her capacity for love, for acceptance of sexuality or her defensive, punitive attitude in this respect, influences the daughter's identification with her in the early stages of the development. During adolescence, while the girl struggles with her awakening sexuality, all these factors come into play more forcefully than before. If the identification is successful the girl becomes capable of accepting her own heterosexual tendencies without fear or defense; and she will be able to accept menstruation without undue protest or regression. If the process of emotional maturation failed the rebellion against the mother continues as a protest against menstruation as well as against other aspects of femininity. Thus, it may develop an incapability of the woman to accept her sexual organs and sexual function with pleasure and this may lead to inhibition and suppression of the organic function of sexual-

ity; and frigidity, functional sterility, menstrual disturbances, as well as obesity may ensue.

THE OVARIAN FUNCTION

The function of the ovaries is to produce the germ cells—ova—and the regulatory hormones by which reproduction is brought about. It is undecided when this activity begins. Although recent investigation indicates that around the age of three to four years, children of both sexes excrete masculine and feminine type hormones—estrogenic and androgenic substances—it is assumed that the ovaries are dormant until the beginning of puberty. On the other hand, there is evidence that estrogenic hormones are produced before the cyclic function develops completely. Maturation may be only partial for some time even though menstruation may occur with more or less regularity.⁵

The physiological cycle of the ovaries begins with the ripening of the follicle; this process produces the follicular hormones—*estrogens*. When the follicle reaches its maturity, lutein cells appear in its wall and the production of the second ovarian hormone—*progesterin*—begins indicating the preovulatory phase; this normally ends with the rupture of the follicle: the ovum escapes its covers and is ready to be fertilized. The cells which originally shaped the wall of the follicle form, after the ovulation, the corpus luteum which produces progesterin. The maximum functional capacity of the corpus luteum is usually attained in about a week after ovulation. After this period, if pregnancy does not occur, the corpus luteum begins to degenerate, the progesterin production diminishes and completely disappears. As a result of this, the uterine mucosa which was prepared for the reception of the fertilized ovum by the effect of the progesterin, breaks down and the menstrual flow starts; this ends the cycle. Usually, however, during the time of degeneration of the corpus luteum, new follicles begin to enlarge, of which one may be destined for the next ovulation. Thus the cycle repeats itself.

The cyclical function of the ovaries governs the behavior of the females of lower mammals causing periodic receptivity—heat or estrus—at specific intervals peculiar to the species. In hu-

⁵ Allen, Dauforth, Doisy, *Sex and Internal Secretions*, Williams and Wilkins, 1939. R. G. Hoskins, *Endocrinology*, W. W. Norton and Co., New York.

mans the operations of these factors are not obvious since the primary biological tendencies are disguised by cultural patterning as well as by modifications due to interpersonal relationships. In spite of this, close observations have revealed that the course of emotions related to sexuality in women is under the controlling influence of the ovarian activity. In a series of investigations the state of ovarian function was established by examination of daily vaginal smears in a group of women during the course of their psychoanalytic therapy.⁶ On the basis of interpretation of dreams and fantasies and other emotional manifestations the phase of the ovarian function was inferred. When the two sets of independently achieved data were compared a definite correlation was found between the ovarian function and the emotional state. Briefly these investigations showed: (1) During the follicular ripening phase, paralleling the estrogen production, an active sexual energy dominates the behavior and brings forth libidinous demands in order to seek contact with the sexual object. As in the lower mammals so in humans the estrogens were likewise found to be playing the basic role, namely to bring about sexual activity. (2) When progesterin comes into effect the direction of the psychosexual energy changes; it becomes directed toward the woman's body as a passive-receptive tendency. The effect is a generalized erotization; the woman appears relaxed, her readiness to receive the male is usually conscious, while the desire for impregnation and for pregnancy is usually expressed in dreams and fantasies only. When preparation for motherhood becomes the goal of the hormone function which parallels the progesterin production, the emotional preoccupation with motherliness becomes manifest.

THE SEXUAL CYCLE

The evolution of the ovarian cycle forces the emotional processes of an adult woman into regulated channels. Beneath all the complex superstructure of human personality there is an ebb and flow of physiological stimuli which directs the sexual needs of woman. This cycle begins with the gradual production of estrogen and parallel with it develops the active sexual tendency, the object of which is the sexual

partner and the aim, coitus. The estrogenic phase is usually accompanied by a sense of well being and alertness. The normal manifestations of heterosexual tendency need not be discussed here. They are easily recognizable in dreams and fantasies, in conscious emotional attitudes as well as in behavior. If the desire is not satisfied, the emotional tension may increase; restlessness and irritability are often signs of thwarted sexual urge in adult women. For the psychologist it is important to recognize the heterosexual tendency in its disguises as it appears in inhibited individuals; then, parallel to the increasing hormonal production the characteristic defense against sexuality can be observed; in infantile persons anxiety, in others, increasing hostility may cover up the heterosexual tendencies.

About the time of ovulation the active sexual energy fuses with the passive receptive tendency and thus creates the highest level of psychosexual integration, i.e., the biological and emotional readiness for conception. If gratification is impossible the increased physiological tension stirs up the suppressed conflicts, which may be expressed through dreams and fantasies, as well as by conscious emotional attitudes, and/or through symptoms. Thus in enhanced libidinal readiness, or, if this is thwarted, in the increased emotional tension, we may recognize the preovulatory phase.

After ovulation occurs the tension is suddenly relieved and a period of relaxation follows. Nothing is more likely to reveal the new phase of the sexual cycle than the psychic apparatus which at this time expresses the emotional reaction to the biological task of reproduction. This is induced by progesterin. While the action of the corpus luteum increases a period comparable to the quiet period in lower mammals develops and lasts for several days. The emotional concern shifts to the body and its welfare. The psychological material corresponding to this period might be summarized as preparation for motherhood. This may be expressed as a wish for or fear of pregnancy, or as a hostile-aggressive defense against it. Analysis of this material usually reveals the striving for identification with the mother; desire for motherhood appears in the psychoanalytic material at the height of the progesterin production and usually indicates developmental resolution of the conflict with the mother. If this level of emotional maturity

⁶Therese Benedek and Boris B. Rubinstein, "The Sexual Cycle in Women," *Psychosomatic Medicine Monograph*, Vol. III, 1942.

is not achieved the psychoanalytic material reveals the protest against mother identification. Conflicts with the mother and/or with the child then dominate the psychological material which may be expressed with great emotional tension or by depression.

Upon the decline of progesterone production the *premenstrual phase* follows. This is often signalized by the reappearance of heterosexual tendency corresponding to the incipient maturation of new follicles. The physiological process taking place in the uterus as well as the emotional manifestations indicate the preparation for menstruation. Parallel with the diminishing hormone production regressive tendencies motivate the emotional behavior. This may account for the fact that the *premenstrual phase* is often described as the recurrent neurosis of women. Very few women are completely free from mood changes and from discomfort during this part of the cycle. The symptom manifestations show great variation. Apprehension of what will happen to one's body, fear of mutilation, recurrence of other infantile sexual beliefs may give rise to anxiety, excitability and to rage-reactions. In other cases, fatigue, crankiness, sensitiveness to being hurt, weeping spells indicate a calmer but not much more agreeable condition. The generally increased excitability of the nervous system—a reaction to the relative ovarian deficiency of this phase—may be responsible for the fact that in these days all needs and desires appear imperative, all frustrations unbearable; the emotions are less controlled than at any other time during the cycle. It is as if the ego, deprived of some of its controlling functions, is permitting repetition of emotions experienced by the individual during her oedipal and puberty development. The end of the sexual cycle is marked by menstrual flow which, ushered in by a sudden decrease of hormone production, continues for several days. Soon after the flow is established the tense and fearful mood relaxes, the excitability decreases. It seems that adult women accept the menstrual flow with emotional relief. The clinical picture of *premenstrual depression* usually prevails longer than the other *premenstrual* symptoms. Although this may be explained on a purely hormonal basis, it is interesting to note that the psychological material can be interpreted as regret over failure in achieving pregnancy. Women then often recall sad experiences, abor-

tions and death; they depreciate themselves and the female genitals which they feel are worthless, and complain about menstruation which is regarded as superfluous, senseless, dirty. This depressive mood usually continues until the new estrogen phase re-establishes itself. After a few days, normally during the flow, the estrogen development begins, and parallel to it a state of well being arises with this, a sexual stimulation suggesting the beginning of the new cycle.

This is indeed a schematic account of the psychic and somatic evolution which constitutes the sexual cycle. Since stimulating and inhibiting factors assert their influence continuously on the sexual development as well as on the mature individual the sexual cycle shows not only characteristic variations in its pattern, but also changes in one and the same individual. The most obvious characteristic of the cycle is its length, that is, the interval between the menstrual flow. The average length is 28 days; some women menstruate in 21–23 day intervals, and others, also within the range of normal, have cycles of 32–35 days duration. There may be variation in the time of ovulation, as well as in the relative frequency of ovulatory cycles—i.e., cycles in which ovulation fails to occur; obviously this is an effect of inhibitory factors. Most revealing for the pattern of the hormonal cycle is the intricate relation between the two phases, estrogen and progesterone, of the cycle. The balance of these two phases determines the length of the cycle and time and duration of the menstrual flow as well as the existence or lack of some symptoms.

Progesterone is the specifically female hormone; while estrogen may be produced in variable degrees from childhood on, progesterone develops only after puberty as a function of the ovum. Its appearance indicates sexual maturation; its physiological and psychodynamic effects are responsible for the cyclical changes. It is therefore understandable that its relation to estrogen production, its deficiency or preponderance, characterizes the variations of the cycle. Here we would like to reiterate that the emotional expression of the progesterone is manifested in feelings related to motherhood, which in their psychological genesis depend greatly upon the girl's relationship to the mother from earliest infancy until maturation. Thus investigation of hormonal cycle as well as psychoanalytic in-

vestigation of the developmental factors revealed that there is a definite inter-relationship between psychosexual development and the hormone cycles. While the pattern of the hormonal cycle unfolds concomitantly with those factors which determine the psychosexual development, the psychodynamic course of the cycle seems to repeat this development in condensed form again and again under the control of the hormonal cycle. Thus the sexual cycle represents in its manifestations, a psycho-somatic unity the function of which is to prepare the woman for her reproductive role.

PREGNANCY

When the aim of reproduction is achieved, and conception has taken place the cyclic function of the ovaries is interrupted for the duration of pregnancy and it is not reestablished with regularity until after the lactation is finished; then the mother's physiological task with one child is accomplished and the cyclic function begins to prepare for the new offspring. Pregnancy, physiologically, is an extremely complex process; it is normal and, at the same time, an exceptional condition which often tests the physical reserves of the woman. Therefore it is not easy to decide which of its accompanying symptoms are purely organic and which may be emotional in origin.

There is not much known about the psychology of pregnancy. Whether or not there is a genuine physiological need directing the woman's desire for pregnancy has been only rarely discussed in the psychoanalytic literature. For a long time Freud's hypothesis that childbearing represents a substitute for lacking masculinity was generally accepted. However, what has been indicated with regard to the development of female sexual function justifies the assumption that the psychodynamic tendencies which prepare for reproductive function represent a genuine quality of the female psychosexual anlage. Observations on little girls, their enthusiastic interest in living toys,—cats, rabbits,—their play with dolls or with their siblings express motherly attitudes earlier than the controlling hormone function develops. Until the woman achieves full functional maturity the primary motherliness may be interwoven with many complicating factors; thus the primary desire for the child—the psychic representation of a biological need, can not be easily demon-

strated. As long as gratification of the biological need for motherhood is fulfilled without interference of human controls one can rarely study the primary psychological factors involved in childbearing. Women, overburdened by childbearing and by the ensuing responsibilities, often complain; although their relationship with their children may be genuinely motherly, the pregnancy appears to them as a function forced upon woman by nature and by man. Only if the satisfaction of childbearing is denied to them does the wish for the child become manifest and the pregnancy desirable. In such instances, whatever the reason of sterility may be, the sense of frustration may change the natural desire for motherhood to a clamoring obsessive demand which becomes the representation of all the combined frustrations of a lifetime; thus, they prove but little about the primary need for motherhood. There is a large experiment going on in our civilization: birth control. Since child bearing became dependent upon individual decision there is better opportunity to observe the genuine response to the physiological conditions of preparation to childbearing. Many women postpone childbearing voluntarily on account of various considerations. These women are not sterile. In such cases we may observe the variety of emotions, the desire and the frustration which occur when the pent up physiological preparation is useless and the emotional tide of motherliness recedes; in the repetition of this process, we may recognize the factors which may lead to sterility and those which become finally satisfied by pregnancy.

The most-often-occurring disturbance of the early phases of pregnancy is the so-called "morning sickness," nausea and vomiting, which may be occasional or persistent. It is interesting to note that this condition does not occur so often nowadays and that, when it does, it is only rarely with the severity hitherto observed. Nausea at the beginning of the pregnancy usually is the effect of the hormonal unbalance. It is not necessarily a sign of rejection of the child and is much more easily overcome if the woman accepts her pregnancy than if she clings to every discomfort in order to prove that she has to suffer from her condition. A placid self-centered contentment is the characteristic emotional attitude in pregnant women and this is observed in spite of transitory complaints, especially in young women. Even women who

were usually tense, nervous, excitable or even accustomed to having anxiety states are surprised about their gratifying calmness during pregnancy. Achievement of this state probably accounts for the willingness to bear children, even in the face of all discomforts. The modern woman who chooses to be pregnant is naturally more aware of this gratification; at least she expresses it more articulately. During pregnancy the woman enjoys the gratification characteristic of the progestin phase of the cycle many times multiplied. Responsible for this is the increased hormone production; added to it comes the fact that during pregnancy the environment also permits readily the self-centered attitude and even favors various kinds of regressive infantile demands of the woman. While she is permitted to have specific gratifications, the regression itself has a function: it seems to pave the way for the mother's emotional identification with her infant. The passive-receptive identification with the child is one of the psychodynamic sources of the mother's tenderness toward the baby; for the mother, the baby is just a part of her loved self during pregnancy and after parturition only slowly does the infant become an object of love, separate from herself.

The physiological preparation for childbearing is the same for children of both sexes, its emotional concomitants naturally have to be the same for the child of either sex. Folklore, however, always tried to predict the sex of the yet unborn baby from the behavior of the pregnant woman. Her symptoms, her facial expression, her carriage and many other things were held to be predictive of the sex of the child to be born. Although statistical investigations would not confirm such assumptions, the fact that these superstitions developed has a psychological significance. It indicates a general awareness for differences in the mother's emotional attitude corresponding to her expectation, to her wish or fear in regard to the sex of her child.

In our civilization, woman's desire to give birth to a boy has many motivations. It is a manifestation of society's evaluation of the male sex, and hence it is not surprising that women may strive with great desire to fulfill it. But more in keeping with woman's emotional needs are other motivations: the love of the husband, the desire to reproduce him or to produce what he values the most, are the healthy motivations

for the desire of having a son. These motivations do not cause the desire for a son to be exclusive. The wish for the son becomes dominant when the woman is afraid of having a daughter. Woman's awareness of or sensitivity to repetition of emotional situations is deeply ingrained. Trained through the monthly rhythm of psychic and somatic events she unconsciously expects repetitions. This may reinforce her apprehension that the struggle which once she had with her mother will be repeated in her daughter's relationship with herself. If her own conflicts have been resolved she is ready and willing to accept her child regardless of sex. The dominance of the wish to have a daughter may likewise have several determinants. It may be that the identification with the daughter appears to the woman easy and without conflicts; or that she may be afraid of her conflicts with a son. Hostility toward the male sex as well as fear of her sexual responses may cause a woman to dread an outbreak of her conflicts if she had a son, and so she might have an exclusive desire to have a daughter. In neurotic women apprehension about the sex of the oncoming baby may become very severe during pregnancy. Fear of the inability to love the child engenders feelings of guilt even during pregnancy. This may cause severe anxiety, and depression. In some cases these feelings may be warded off until parturition. Then the pain and suffering during delivery, the fear that she might have died, may activate and reinforce hostility toward the child. The sudden change in the hormone household is another factor favorable to depressive emotional states. The young mother who expected to be happy in her motherliness finds herself fatigued and lacking emotions; this alone is a disappointment which usually is overcome in a few days, when the young woman, loved by her husband, recovers from the physiological "let down." If the disappointment about the sex of the infant is added to this depressive state, the hostility toward the child may become manifest. In severe cases, fear of this hostility and guilt about it may cause depression or psychotic reactions. But in most cases, we observe only a more or less serious rejection of the child. In such fashion is the seed of the neuroses of the new generation planted. It is not our intention to describe here motherliness and its manifestations. However, it must be emphasized that the mother's life

encompasses her children, not only in the routine of everyday life. In this close interrelation the mother relives her own emotional needs, also her own conflicts—and thus, she determines the emotional development of her children.

The psychodynamic conflicts which force a woman to fear her sexual function may influence reproductive capacity in various ways. (1) In cases of chronic deficiency of the ovarian function the emotional attitude remains infantile and inhibited. These women usually fail in getting sexual partners. (2) The woman's total personality remains sexually attractive but her orgasmic capacity is inhibited; she may be completely or partially frigid. The signs of emotional frustration are more obvious in the latter than in the former deficiency. Orgasmic capacity is not a prerequisite for ovulation and for perfect reproductive function. (3) Functional sterility is a condition caused by other than anatomical disorders. Although we assume that in these cases the primary emotional conflict resulted in the fear of pregnancy and hostility toward a child, the desire for the child may remain active and alive; these women suffer from a sense of severe frustration if their attempts to become mothers fail. The desire and the failure puts the woman under a strain of an emotional vicious circle which is apt to intensify psychosomatic conditions. Several cases have been reported in which this vicious circle was interrupted; the women became capable of having their own child after one was adopted. This indicates that, after the women were able to overcome the fear of a child, their reproductive function recovered.

THE MENOPAUSE

The active, reproductive period in women lasts some thirty-five years. At about the age of forty-seven, on the average, it comes to an end, and with it menstruation disappears.

Menopause can be induced artificially by removal of the ovaries. In young girls such an operation interrupts the further sexual development but does not cause the characteristic symptoms which occur if the ovarian function is interrupted suddenly in a woman of childbearing age. The symptoms in the latter can be alleviated by substituting hormones. This can be taken as proof that the disappearance of the hormones causes the symptoms of menopause.

These symptoms vary greatly. The average healthy person, especially if she has had several children, will notice only moderate discomfort, while women whose sexual life was unsatisfactory and who did not have children may suffer more acutely. In such cases it often appears as if the ovarian function instead of slowly abating becomes irregular and the hormonal unbalance is then the cause of the severe symptoms of climacterium.

The symptoms of the menopause are psychosomatic. The hormonal regulation fails and with it signs of irritation of the sympathetic nervous system occur: irritability, restlessness, insomnia, and various manifestations of vasomotor lability are the most common symptoms. The well known hot flashes are sudden vasodilatations accompanied by discomfort. The intensity of these symptoms, as well as the woman's immediate responses to them, depends mainly upon her total personality. This will decide whether she can accept the new phase of her life gracefully or whether she will rebel against it in a futile struggle. The expectation of the "change of life" plays a great role in woman's life, and it often troubles her emotions even as early as in her late thirties. While the manifest behavior shows only a fear of becoming old, a more detailed psychological observation reveals a repetition of the emotional struggle she had against menstruation during adolescence; this time, paradoxically for the purpose of holding on to a function she once feared and detested. This shows the emotional over-evaluation of the menstruation itself. Since it was the sign of maturation when it came, its disappearance not only indicates to the woman that she cannot have children any more, but it also activates the fear that she cannot have sexual gratification any more. This, however, is not necessarily the case. A considerable amount of eroticism may persist after climacterium depending mainly upon the totality of libidinal experiences and practices throughout life. A well-balanced, well integrated personality takes climacterium in her stride; her emotions are established in her family, in her community group, in creative activities for which she can strive even more energetically after her reproductive task is finished than she did before; these gratifications will enable her to rise above the regressive phenomena which makes this period of life so critical for neurotic women.

We have described in detail the emotional manifestations accompanying the low hormone level during the premenstrual-menstrual phase of the cycle. The menopause is merely the repetition of that, only more severe, since the hormone decline will not be relieved in a few days. Hence the depression as well as the sense of frustration becomes more painful, the regressive manifestations—corresponding to the decreased hormonal function—more lasting. One example of this is that women of this age indulge in eating and gain weight. Emotionally, the woman's capacity to love, to be interested, to concentrate may decline. Physiological signs of the lacking estrogen function may develop also; some women may experience a slight degree of masculinization; the voice may become deeper, hair growth on the face or on the legs may become marked. Again it depends on the personality of the woman to which aspect of the decline in herself she may respond with deep dissatisfaction, with the feeling: "This should not happen to me." Such disappointment in oneself engenders inferiority feelings, and self accusations which form the core of the emotional disturbance in climacterium. In many instances they are overcome by the existing productive aspects of the woman's life; if not, they may develop into more or less severe depression. It is generally known that so-called "high strung individuals" are more apt to have severe symptoms during climacterium than others. The reason for this is: a "high strung individual" is one who cannot take frustrations. At climacterium, however, she is faced with a double frustration; she senses her declining functions and she is aware that gratification from the external life may be limited or thwarted. If she has not already learned to adjust herself to such events, the climacterium concomitant with a regression of sexual functions may reactivate those conflicts which were important in earlier developmental phases, thus engendering turbulent emotional situations. Ordinarily the woman adjusts readily to one set of frustrations, even if sometimes the adjustment takes longer and is at the cost of some changes in personality. Only if external disappointments occur at a time when the woman in awareness of inner decline feels incapable of mastering the situation, does she become seriously ill. Normally, however, women adjust to this change of life and continue a

well integrated socially productive life for many years, long after the reproductive function has been terminated. Women's life expectancy is, after climacterium, longer than that of men in the corresponding age group.

SUMMARY

The woman's life—more markedly than the man's—is divided into periods which are defined by her reproductive function. The first period lasts from infancy to adolescence. During this, the relationship to her mother will determine the development of heterosexual attitudes and the emotional acceptance of the propagative function. The second is the reproductive period. From menarche to menopause, in cyclic intervals the woman gets ready for conception, failure of which results in the menstrual flow. From one menstruation to the other evolves the sexual cycle, during which corresponding with the hormonal stimulation, is repeated the rise and decline of emotional integration of the psychosexual maturation. After a child is born the mother's psychosexual life is partially externalized, it encompasses the child. With the daughter, more directly than with the son, the mother repeats those emotional attitudes which originally determined her own emotional development. Living her life with her children again gives the woman the chance for final personal integration in mature motherliness. The accomplishments of the reproductive phase will determine the manifestations of the climacterium and also her emotional life after the menopause.

THERESE BENEDEK, M.D.,
Chicago, Illinois

PSYCHOSOMATICS.—*Definition:* The term "psychosomatic" implies that either in the observable manifestations or in the constructed motivation of healthy or pathological functioning a correlation can be established between "psychological" phenomena, such as reactions of fear or outbursts of anger, on the one hand, and either functional or irreversible structural alterations, such as rapid heart rate, peptic ulcer or brain damage, on the other.

The term "psychosomatic medicine" was coined in 1939 at the time the *American Journal of Psychosomatic Medicine* was founded. It is obvious, however, from its problems and methods that psychosomatics represents a syn-

thesis of several streams of psychological and medical investigation.

BASIC CONCEPTS AND THEIR DEVELOPMENT

Function of the Brain—Clinical and Post-Mortem Observations—Experiments. One of the basic ideas in psychosomatics is the correlation between the psychological functions and the functions of the brain. This is equally fundamental in establishing relation between brain damage and psychosis, as in general paresis; or between stresses of life situations and bodily illness, such as hysterical paralysis or bronchial asthma. The reaction to life stresses takes place in the patient's brain, where the chain of events starts—nervous impulses, metabolic effect—which finally lead to bodily illness.

The Function of the Brain. The clear establishment of the functions of the brain and its parts occurred rather late in the development of science. It was based partly on correlating clinical and post-mortem observation, which was becoming a general research procedure in medicine. The cerebral hemispheres are "the principal seat of the immediate cause of sleep, of dementia, of apoplexy, of melancholia and of mania." This was the conclusion of Rolando (1808). In another part the development was based on experimentation, namely, the removal of various parts of the brain by operation, followed by observation of the functions of the surviving animal. "The functioning of the cerebral lobes is willing, judging, remembering, seeing, hearing—in a word, perceiving." If the lobes are removed, the animal may lie still until it dies of starvation. He is blind and deaf. These were some of the observations and conclusions of Flourens (1822).

Reaction Time—Speed of Conduction of the Nerve Impulse. A stimulus (e.g., light) is presented to the subject, who is instructed to signify with a simple movement, e.g., raising a finger, the instant he perceives the stimulus. The time elapsing between the giving of the stimulus and the movement made in response to it is the reaction time.

On a nerve-muscle preparation of the frog, the nerve is stimulated electrically next to the muscle, and the time elapsing between the stimulus and the contraction is measured. Then the nerve is stimulated at a point farther from the muscle, and again the time interval is measured. The difference between the two intervals

gives the time it takes the nerve impulse to travel the distance between the two points on the nerve. A man's reaction time is measured by giving an electric shock to his foot. His reaction time is measured again, now giving the electric shock to the upper part of his thigh. The difference between the two reaction times gives the time it takes for the nerve impulse to travel the distance between the two points.

These observations by Helmholtz (1850), although methods as well as results have become more complex since, represented a turning point in man's approach to the functioning of the nervous system. They represented an experimental and quantitative method proving the existence of measurable physiochemical processes in the nervous tissue, thus giving concrete body to the idea of psychophysical correlation.

Relationship Between Intensity of Stimulus and Intensity of Sensation. A screen is illuminated with a hundred candlelights. The subject is instructed to state if and when he notices an increase in illumination. It is then found that an increase of one candlelight is necessary for the subject to notice an increase in the intensity of light. If the screen is illuminated with two hundred candlelights, an increase of two candlelights represents the minimum noticeable difference.

Experiments of this type were first done by Weber (1834) and then later, in great detail, by Fechner (1860). It was Fechner who formulated his results as the "law of psychophysics," stating that *geometric progression in the intensity of the stimuli is paralleled by arithmetic progression of intensities of sensory experience.* This quantitative formulation holds more or less accurately only for the middle range of intensity and does not hold for very intense (or very weak) stimuli. This procedure represented another important quantitative experimental step toward the exploration of the relationship between "psychological" and physical processes.

Recording Bodily Changes During Emotional Reactions. Changes in the volume of the extremities depend mainly on the relative filling of the blood vessels. If the blood vessels (mainly arterioles) contract, the volume diminishes. Such volume changes can be recorded by enclosing the extremity, airtight but not under pressure, in a glass tube. The extremity communicates its changes of volume to the air in

the tube, and changes are recorded graphically by a tambour.

If a relaxed subject is asked to perform some task under pressure, particularly if his anxiety is aroused that he might fail at the task, a diminution in the volume of the extremity can be observed as registered by the plethysmograph. This type of experiment was first performed by Mosso (1884). Similar experiments were performed on changes in pulse rate (acceleration) and on blood pressure (rise) by Lehman about the same time (1892). These developments went hand in hand with the accurate methods of observation in medicine and the developments of instruments for the recording of bodily functions in illness. The experiments here mentioned represented another very significant step in the attempt to correlate psychological and physiological events and give the latter quantitative expression. The general tendency here described found a crystallized and systematic expression in the establishment of the first psychological laboratory by Wundt (1879).

THE PROBLEM OF THE PART AND THE WHOLE

Localization of Motor Function in the Cortex of the Brain. It was stated in the previous section that Flourens correctly observed and concluded "The functioning of the cerebral lobes is willing, judging, remembering, seeing, hearing—in a word, perceiving." He assumed, however, that the cerebral lobes performed these functions as a unity and that there was no further differentiation in them as regards function and localization. It was not long after, however, that further differentiation was proved in the central nervous system.

The first such development occurred on the basis of clinical and post-mortem observation. It was found that a man who could use the musculature of his articulatory organs for other purposes, and who was intelligent enough to speak, nevertheless was not able to speak. He had lost this ability thirty years before he died of a gangrene. On post-mortem examination, a lesion was found in the third frontal convolution of the left cerebral hemisphere. Broca, who made this discovery, considered this area a distinctly localized motor speech center (1861).

Additional proof of more distinct differentiation was furnished by experimental investigation. If the animal's brain is exposed and the

cortex is stimulated with a relatively weak electric current, an area is found in the anterior central gyrus, the stimulation of the various points of which produces isolated muscle contractions in various parts of the body. Thus respective areas can be found for the muscles of the arms, the legs, the neck, and the face. (Fritsch and Hitzig, 1870.)

Broader View of Localization—Disturbance of Function Is Complex. Similar areas of localization were found for vision, hearing, perception of tactile stimuli. The tendency then predominated to consider these various areas as functioning independently of each other and to consider the functions as distinct isolated faculties. The formulation as regards speech defects then was that there is an entity of motor aphasia (the individual understands speech fully but is not able to speak), auditory aphasia (the patient hears what is said to him but does not know the meaning of words), alexia or visual aphasia, consisting of the defect in understanding written language, and agraphia (the defect is in the ability to write). Further investigation, however, showed that this was not a correct formulation either. It was found that no case of aphasia ever presents circumscribed speech defects. Varying defects of all forms of speech exist in every case, though one form usually predominates. Nor is the defect limited to speech, but is likely to affect other areas of function. For example, in one form of aphasia the individual can speak but is unable to organize words into a correct sentence. An individual with such a difficulty may lose his sense of direction and be unable to plan how to get from one place to another. (Head, 1923.)

Thus, on the basis of the findings mentioned, it was obvious that the complex synthesis has to be effected between the function of the isolated parts and the function of larger complexities, that is, the function of the whole. On this more sophisticated level, the concept of unity was revived.

Concept of Units of Function in Psychology. A similar development took place in psychology and psychopathology. At one period the prevalent assumption was that the unit of psychological processes was the "idea." Ideas are such things as are "expressed by the words whiteness, hardness, sweetness, thinking, motion, man, elephant, army, drunkenness, and others." If we can divide what we know consciously at

any given time into components, we have ideas. Ideas become combined with each other. This is what is meant by association of ideas. Ideas are built up out of sensations. The laws of association are similarity, contrast, and contiguity. (Plato, 438 B.C.; Aristotle, 340 B.C.; Locke, 1690.)

Faculty psychology also represented an approach characterized by the assumption of distinct and separate phenomena, although grouped into broad categories. The three main faculties of the mind were (1) cognition: sensation, perception, thinking; (2) feeling: being pleased or pained; and (3) conation: willing and acting.

A combination of the physiological and psychological unit approach is characterized by the assumption that the reflex, particularly the conditioned reflex, builds up even the most complex psychological behavior. (Pavlov, 1903; Watson, 1916.) A simple reflex is a muscular or glandular reaction to a simple stimulus, the impulse being conducted by way of the reflex arc, consisting of at least one afferent and one efferent neurone. The conditioned reflex is a reflex occurring in response to a substitute stimulus as a result of experience. In the former the cortex of the brain is never involved. In the latter it is almost always involved.

Concept of Patterns and of Personality in Psychology. All of these observations represented important advances and led to significant experimental and practical applications. The broader approach is represented by the assumption that psychological events are interrelated and occur in patterns ranging from simpler to greater complexity. The complex or total reaction contains principles which are not contained in the details alone. (Wertheimer, 1912; Köhler, 1917; Koffka, 1921.) Such a principle is illustrated, for example, by the figure-ground relationship. Thus, if there are a lot of varicolored dots on a page, and a group of them all of the same color and in close proximity form the shape of the figure 4, then this latter pattern stands out as the figure and the rest recedes into the background. A simple action, such as raising one's arm, can be looked upon in a similar manner. The action forms the dominant event, but in addition to that, the rest of the body musculature is so contracted as to form the proper condition of balance, the background, for this event.

The general investigative effect of this ap-

proach is that many aspects of clinical and experimental situations are observed and evaluated and relationships established. Returning for a moment to the behavior of brain injured patients, the following can be observed: Patients with severe brain injuries get visibly disturbed and may tremble all over if they fail in solving a task such as an arithmetical problem. As a result they may lapse into complete unconsciousness. Such a patient may try to defend himself against the onslaught of any task or stimulus with which he cannot cope. As a result he may shun the company of other people, he may constantly engage in self-chosen activities, and he may develop excessive orderliness so that he will not get confused by the problem of where to find things and how to utilize them. Thus all these symptoms can be explained on the basis of a total personality reaction—wanting to escape distressing, perplexing situations. (Goldstein, 1918.)

Broadening of Concepts in Psychiatry—Psychoanalysis. In psychiatry, the development toward broad and embracing concepts is represented first by the approach of classifying disorders in larger categories instead of isolated symptoms. In contrast with viewing various disorders as circumscribed disturbances—e.g., the patient having a delusion of sin and guilt (the patient has the delusion that he has committed the unpardonable sin)—broad disturbances of many aspects of his functioning became grouped together—e.g., under the concept of manic-depressive psychosis. This disorder, then, is characterized by recurring periods of depression and/or elation. In the former, the patient is depressed, is slow in his thinking, speaking, and acting; he is constipated, he loses weight, and has feelings of worthlessness and guilt, often with delusions. He has a dry mouth with a slowed secretion of saliva. In the manic phase, he has flight of ideas, he is overactive, talkative, excited, elated, witty, and often irritable. He may be self-aggrandizing with delusions of grandeur. (Kraepelin, 1895.)

Psychoanalysis, with the method of free-association and dream analysis, established the relationship between a wealth of psychological details manifested by the normal or the sick individual. This integration was accomplished through the concepts of dynamic strivings. This can be illustrated in connection with the manic-depressive psychosis discussed above. The de-

pressive phase of this psychosis has similarities to the normal phenomenon of mourning, in which a love object is lost, and the individual finds it difficult to detach himself from, and go on functioning without, the love and support of the lost one. In depression there is also such a loss, not necessarily in actuality but psychologically. The patient, however, makes himself responsible for this supposed loss because of his hostility toward the love object on whom he is emotionally dependent. The feeling of guilt and worthlessness comes from these qualms of conscience. The elation in the manic case is the opposite of depression. It is an attempted solution of the pain and suffering of the depression. The patient is in flight from, and throws off, his conscience. To accomplish this, he of course has to over-reach himself, and the elation represents the great relief from the burden of suffering and an enjoyment of all the forbidden and feared strivings which the patient had previously kept in check. (Freud, 1916.)

REACTIONS TO LIFE SITUATIONS

Brain Lesions and Toxic Processes. It has been said in the first section that psychological phenomena are to be considered as functions of the brain, the latter involving secondarily the rest of the body. Therefore, "introspective" and "physiochemical" events in the organism are to be considered different manifestations of the same process. The modern concept of "psychological" reactions includes both manifestations. Of necessity, introspective experiences—e.g., experiences of fear, fantasy, being hurt—are obtained and communicated by different methods than observations of "objective" phenomena—e.g., increase in heart rate or running away from a situation. The two types of data are correlated with each other and organized into such concepts as reaction pattern and personality.

It is obvious that the nature of these events is quite different both as to quality and as to determination if the event is initiated by gross structural lesion in the brain or the introduction into the organism of a toxic substance, on the one hand, or such events as a threat to life or loss of a loved one, anxiety and mourning, on the other. It is traditional in medical history to speak of the former as organic and of the second as psychogenic. Aristotle (340 B.C.) observed that the individual often manifests little

fear in situations in which one would expect him to react with great emotion, and at other times reacts with strong manifestations of great fear or anger with little provocation. He attributes this to differences in the state of the body. He also observed that at times the individual manifests and experiences fear when there is no objective reason for it. He relates this to mental causes. The relative emphasis on these two approaches to psychological and somatic phenomena is an old one.

The problem continues up to the present day and can be traced through the development of medicine. The statement, "Every mentally ill person is also physically ill" (Friedrich, 1839), implied that the ultimate cause of mental diseases is in the bodily pathology, particularly that of the brain. This approach led to the first appearance of the term "somatopsychic" medicine. (Jacobi, 1838.) The other orientation spoke of the "psychophysical totality of man." "Whenever abnormal psychic manifestations are present, we deem it a mental disease. It has its roots in the psyche insofar as the latter uses sense organs. It is also rooted in the body insofar as the latter is the organ of the psyche." (Feuchtersleben, 1838.) This author maintained that the consideration of psychological factors is of much greater value than apothecary mixtures.

Cause and Treatment of "General Paresis." In the development of psychiatry, both approaches have made great causative and therapeutic contributions. An example of the primary and predominant "somatic" causation is general paresis, which is due to syphilis of the brain. It was first concluded on the basis of case histories that this was the situation. Then the presence of treponema pallidum was demonstrated in the brain. (Noguchi and Moore, 1913.) The illness was almost universally fatal within a year and a half after its inception. The illness has become treatable with the induction of malarial fever paroxysms (Wagner-Jauregg, 1918); in two-thirds of the cases the patient either fully recovers for practical purposes or improves sufficiently to return to social existence. Even in general paresis, of course, there are "psychogenic" determinants in the symptomatology. Thus the delusions of grandeur observed can be considered as partly determined by a reaction to the failure of some of the directly damaged functions such as memory and reasoning, and

further to the previously unconscious trends toward self-aggrandizement which in turn were based on feelings of worthlessness, rejection and failure and in part represented restoration of the infantile omnipotent outlook on the world.

The Neuroses. The primary psychogenic approach made its great causative and therapeutic contribution to the disturbances commonly referred to as neuroses. The most important and influential development in this direction was psychoanalysis. It was discovered that neurotic reactions had a "meaning," that is, they were translatable into common, everyday psychological terms. They were the manifestations of largely unconscious processes—that is, of attitudes, impulses, strivings—which the subject did not know and of which he was afraid and did not want to be aware. These conflicting impulses could be characterized as pleasure striving, fear, hostility, conscience, ideals, guilt, dependency needs, and need for self-esteem. The difficulties were traceable to both developmental and current conflicts. If, in the process of the therapeutic relationship, the patient could be made aware of his unconscious reactions, he could relive his conflicts with a new and favorable solution, his reaction patterns changed, and his neurosis was cured. (Breuer and Freud, 1893; Freud, 1906.)

Of course, the patient who exhibits neurotic reactions suffers from physiological disturbances of more or less the whole organism also. Constipation, diarrhea, rapid heart rate, cold extremities, diminished activity because of fatigue, inadequate sexual performance influence in subtle ways the general metabolism and circulation. In extreme instances, neurotic hyperventilation—continuous deep breathing—may lead to such diminution of the CO_2 content of the blood as to result in alkalosis and tetany. The latter consists of sustained spasms of the upper and lower extremities. (Talbot, Cobb, Coombs, Cohen, and Consalazio, 1939.)

Combined Approach. There have been attempts made in research to combine both approaches in investigating the combinations of bodily types and mental traits, together with tendencies toward types of mental disturbances. Thus three types were differentiated: "pyknic," "asthenic," and "athletic." Pyknic type is characterized by overweight, large round chest, and short neck; the asthenic, by underweight and flat chest; the athletic, by long limbs and well-

developed muscles. Patients with manic-depressive psychosis are more often pyknic; those with schizophrenia, asthenic. (Kretschmer, 1925.) Similar is the grouping established on the basis of standard photographs of the three views of the naked subject: of "endomorphism," "mesomorphism," and "ectomorphism." Endomorphism is the dominant component in soft, round people with big viscera (jolly, fat man); mesomorphism, that in those with much muscle and bone (burly athlete); ectomorphism in those with leanness, fragile bones, large skin surface and brain (nervous bookworm). (Sheldon, 1940.) A more circumscribed relationship between toxic reactions and neurotic reactions to life problems is illustrated by this observation: asthma (attacks of difficulty in breathing) is often maintained in response to life stresses in individuals who manifest altered reactivity to certain substances, e.g., to contact with animal hair or ingestion of milk.

RELATIONSHIP BETWEEN ORGANISM AND ENVIRONMENT

Reactions of the organism always have to be described in the type of environment in which they are being studied. (Lewin, 1936.) Certain processes occur in the organism regardless of the type of environment, although they change depending on the environment. Other phenomena occur only under certain environmental conditions. The metabolic changes in the organism occur under all circumstances, and in vertebrates oxygen is consumed. These processes may vary tremendously in heat or cold, during activity and rest. One would assume that breathing movements would have to occur as long as the organism is alive. However, if the subject is placed in a chamber in which the air pressure varies ± 55 mm. mercury around the atmospheric pressure twenty to thirty times per minute, adequate gas exchange takes place without lung movement, and the respiratory movements cease. Under different circumstances, of course, the cessation of respiratory movements would be accompanied by alarm. Under these circumstances, that reaction is absent. (Thunberg, 1924; Barach, 1940.)

The standardization of experimental stimuli is necessary in exact experiments. However, the significance of an environmental situation (stimulus) for the organism may differ from individual to individual or even for the same

individual at different times. Food or sex situations have different values for the organism when it is in need of satisfaction and when it is sated. A sudden sound is a different stimulus for one who works daily with comfort in a noisy place than for one who, as a result of traumatic experiences, starts violently at any unexpected noise. There is enough uniformity in a large series of stimulus situations for most individuals to make experiments with identical stimuli statistically significant. A more effective way, whenever possible, is the use of situations, varying if necessary, which have similar significance for different individuals. Thus, interviews touching on emotionally charged life situations are the best means of inducing stress in the experimental subject. (Mittelman and Wolff, 1939.)

INTEGRATION OF MULTIPLE FACTORS

Psychobiology. It has been stated that some pathological processes start with lesions in the brain or toxic processes in the body, but there are evidences of total personality reactions to the disease process also. In other pathological processes the disturbance starts with stress reactions to life situations and there are evidences of disturbance in physiological economy of the organism. In some pathological processes the general make-up of the organism or some biochemical experience seems to facilitate the development of disturbances of certain types. It has further been stated that manifestations, observationally or experimentally circumscribed, have to be brought into relationship with other manifestations of the organism; further, the functions of the organism have to be viewed in their environmental setting.

A convenient way to list the various causative factors in illness and to give rough, relative, quantitative significance to them is to assign zero to four plus to genogenic (hereditary), histogenic (caused by visible lesions), chemogenic (toxic, or deficiency of some agent), and psychogenic (reaction to life situations) factors.

A woman with a healed abscess of the brain began to have convulsions. Considering her very difficult home situation she was treated psychologically, and stopped having convulsions. Obviously in this case the psychogenic factor was as important in maintaining the illness as the histogenic factor. (Cobb, 1944.)

A comprehensive synthesis of both

normal and pathological phenomena is represented by the concepts of psychobiology. The organism reacts to life situations as a dynamically integrated whole. The nature of the reactions is determined by the individual's personality, the situation, the individual's constitutional make-up, and past experiences. The function of the vegetative organs is part of the total reaction. Characteristic psychopathological conditions, such as manic-depressive psychosis or schizophrenia, are to be viewed as "reaction types" determined by the above integrated factors. (Meyer, 1905.)

PSYCHOSOMATIC METHODS OF INVESTIGATIONS AND RESULTS

Reactions to Life Situations—Clinical Observations. In clinical observations, the investigator interviews the patient frequently, observes the latter's behavior, and records his introspective experiences occurring in response to day-to-day events including the therapist's person and comments. Constructions based on these observations are "tested" over a long period of time on the basis of the patient's reactions to new events as well as his reactions to the constructions conveyed to him by the investigator. The problems handled are complex, and it would be difficult to create uniform experimental situations and to reduce the variables sufficiently to handle them with formal statistical procedures. These observations and constructions acquire regularity by the repeated occurrence of the same sequence of reactions in single patients as well as in several patients manifesting similar symptoms. In the course of the evolution of psychoanalysis, correlations were observed between various psychological and psychopathological phenomena on the one hand and bodily complaints and observable changes in the bodily function on the other.

Anxiety and Changes in Bodily Function. A correlation was observed between anxiety reactions and the following physical complaints or observable phenomena: fast beating of the heart, excessive sweating, diarrhea, vomiting, dizziness, trembling. The correlation is based on the following types of observation: The phenomena occur simultaneously with the experience of anxiety, or the phenomena occur in the same individual in situations in which usually attacks of fear occurred—e.g., in a wife after disapproval by her husband or after inter-

rupted sexual intercourse—or it is observed in some individuals, without experience of anxiety occurring at any other time, in situations in which other patients usually experience anxiety. (Freud, 1892.)

Pleasure Strivings and Guilt and Changes in Body Function. It was observed that together with the arousal of certain predominantly repressed strivings and fantasies certain bodily changes occur. Oral erotic desires, or disgust in reaction to them, may be correlated with choking sensation in the throat, coughing, and vomiting; genital excitement and desire for masturbation with bed-wetting; desire to bear a child with abdominal pain and enlargement due to accumulation of gas. These connections are traceable to childhood interests and experiences. The bodily symptom represents a disguised gratification of the forbidden desire as well as self-punishment resulting in suffering as a result of guilt. (Freud, 1905.)

Relationship Between Hostile Reactions and Changes in the Body Functions. It was observed that attacks of asthma may occur parallel with conscious or unconscious reactions of anger. Such reactions may occur in dreams of violence (Dunbar 1938, Deutsch 1939, French 1939). Arterial hypertension may be correlated with sustained hostility. (Alexander, Saul, 1939.)

Inter-Human Relations, Personality Traits, and Bodily Functions. Two types of relevant observations are significant. (a) Certain character traits may be patterned after various physiological functions. Dependency and the desire to be taken care of are patterned on the desire and pleasure in being fed, as the infant is cared for. Stubbornness or miserliness may be patterned on the stubborn desire to retain the bowels, or cleanliness and meticulousness as a reaction formation to the desire to play with excreta as a result of strict and premature training in cleanliness. (Freud, 1908; Abraham, 1924.)

(b) The individual's self-evaluation and his evaluation of the environment is determined by life-experience, particularly by the vicissitudes (anxiety) of his relation with other individuals from infancy to adulthood. Such vicissitudes are frustration, rejection, being made to feel worthless, and being made to obey without reward. The personality traits resulting from these may be a boundless desire to be looked after and submit, to dominate, oppress, and hurt other

people, to excel all others, or to be independent and reject love. (Adler, 1912; Freud, 1926; Fromm, 1936; Horney, 1937; Kardiner, 1937; Rado, 1939). The disturbed function of the organs may be an expression of these strivings or may occur concomitantly with the reaction of fear, anger, and guilt if the strivings are thwarted. Thus a hard driving, emotionally detached man may develop gastroduodenitis and peptic ulcer when he fails in his enterprise and in addition feels unsupported by his wife whose affection he himself had rejected. The gastric disturbance (over-function) represents an expression of the desire to be fed (Alexander, 1934), an attack on the frustrator, a feeling of being counter-attacked in a helpless state, guilt and a plea for mercy. (Mittelman and Wolff, 1940.)

Three important concepts in clinical thinking are those of helplessness, conflict, and "internalization." Helplessness implies a feeling of catastrophe in case of anticipated abandonment or anticipated attack. Conflict implies the existence of clashing strivings in the individual leading to sustained tension. "Internalization" implies the acceptance by the individual of the demands and restrictions of the environment finally as dictates of his own conscience and as his own ideas. Lastly, the clinical approach considers the individual as a whole in relationship to the environment.

Life Situations and Precipitation of Illness. In reviewing the patient's life and his illness, a temporal relationship can be found between stresses of life situations and periods of suffering. In a large number of patients, life crises—e.g., death in the family, separation, occupational failure, marriage—precede the onset of the disturbance; in others, a sustained situation of stress obtains—e.g., marital unhappiness, discrimination, disappointment in the children. The effects of such situations are cumulative and when the patient reaches the limits of his endurance or loses hope of betterment, the illness begins to dominate the picture. These relationships may be presented graphically in the Life Chart by putting side by side in chronological order major life events and manifestations of illness. (Meyer, 1905.)

EXPERIMENTAL OBSERVATIONS

Emotional Reactions and Bodily Changes. The concept of an emotional reaction implies

(1) the individual perceives something in the environment; (2) he has an introspective experience; (3) there are concomitant bodily changes; (4) an alteration in his behavior follows. This last alteration may be merely an impulse or it may be paralysis. Vegetative changes may be concomitants of an intense conscious experience. At other times strong conscious experience may occur without much concomitant change or the change may occur without conscious experience. Such techniques as free-association and dream analysis may be needed to adequately clarify the reaction. Further, the dominant vegetative reaction, e.g., gastric or circulatory, may vary from one individual to the next with similar introspective experience. Thus emotional reactions cannot be equated merely with a vegetative change.

Physiological changes that occur during emotional reactions occur also during physical alteration in the environment or during muscular activity. Thus, a rise in pulse rate, fall in finger temperature, rise in blood pressure, increase in sweat secretion and respiration occur both during physical exercise and during emotional stress (anger, anxiety), as well as during such a complex experience as sexual orgasm. It is understandable for this reason that in individuals with personality disturbances the symptoms may appear during physical exercise or during changes in the physical aspects of the environment. Thus, severe attacks of palpitation and rapid pulse, as well as pain in the region of the heart, may arise regularly connected with emotional stress during muscular effort. Individuals with a tendency to cold extremities connected with emotional stress may suffer badly on account of the cold extremities in cold weather.

Vegetative changes during emotional reactions occur simultaneously in several organ systems. Thus during lying (fear of detection) there is increase in sweat secretion (psychogalvanic reflex), rise in blood pressure, and alteration in the rapidity and shape of respiration. Experimental observations of the functions of various organ systems will be presented in connection with special syndromes. Here the changes in the sweat secretion of the palm of the hand (psychogalvanic reflex) will be discussed, a function which has been recorded in a large variety of standardized experimental situations.

The Psychogalvanic Reflex (PGR). The psychogalvanic reflex consists of lowering of skin resistance during emotional reactions due to increase in sweat secretion. One electrode is placed on the palm of the hand, the other on the forearm. The change in skin resistance is measured on the basis of the movement of the galvanometer needle while an unchanged amount of electric current is flowing through the body. (Féré, 1888.)

In the course of three sittings, 13 subjects were presented 150 stimulus words intended to run the gamut from very pleasant ("darling," "vacation") through indifferent ("basket," "make") to very unpleasant ("suicide," "vom-it"). After each stimulus word, the subject reported its pleasant or unpleasant effect on him, using a five-point scale. Meanwhile a galvanometer was registering PGR (Dysinger, 1931). Pooling the results from the 13 subjects (so far as comparable), the PGR was smallest, on the average, when the stimulus word was "indifferent," as seen from the mean PGR readings:

Effect of Stimulus:

Very Pleasant	129
Pleasant	98
Indifferent	79
Unpleasant	101
Very unpleasant	147

SD_x for these values is about 6; the unit is arbitrary.

It seems that PGR may occur during any kind of emotional reaction but is liveliest during startle or "tension." (Landis and Hunt, 1935.) The increased PGR with either pleasantness or unpleasantness is particularly interesting and parallels some observations on other vegetative phenomena.

There is no adequate formulation as regards the difference in the total organismic reaction during unpleasant experience, e.g., fear and anger, on the one hand, and satisfying and pleasurable experience on the other. The difference may be in the total constellation of vegetative, and at present unrecordable, phenomena in the nervous system. An important difference between healthy and pathological reactions may further be in the intensity and the duration of the reactions. Satisfactory pleasurable experience and passing fear or anger are ultimately followed by relaxation and reestablishment of homeokinesis (homeostasis). In severe enough anxiety states and states of resentment and

frustration, such restitution never adequately follows.

In a series of experiments, repeated startle was produced in subjects by loud, rough noise on successive days. It was then found that on successive days during the anticipatory period, i.e., after the electrodes were applied and the subject was waiting, the skin resistance was progressively higher. In other words, anticipatory tension, and with it the sweat secretion, on successive days, was progressively less. The reaction to noise was present on each day, but also diminished progressively. (Davis, 1934.) These experiments illustrate graphically how the organism adapts itself to a new situation, the vegetative reactions lessening with diminishing anxiety.

Patients suffering from various psychoses manifest a diminished psychogalvanic reactivity both to relatively neutral (e.g., "What day is it today?") and to crucial ("Do you hear voices?") questions. In this respect a record can be considered abnormal if no reliable PGR is elicited by fifty per cent or more of the questions asked. In a series of 100 psychotic patients studied, eighty per cent showed such deviation. The incidence was highest among catatonic schizophrenics (maximal withdrawal from the environment). The deviation was also present in manic-depressive psychosis and general paresis. (Hoch, Kubis, and Rouke, 1945.) Resistively hostile as well as perplexed and evasive patients often show a transient rise in systolic blood pressure in response to questions when there is no psychogalvanic response. This indicates that there is an alteration in the autonomic balance (see later) during psychosis—not simply a general absence of response. (Solomon, Darrow, and Blaurock, 1939.) Adequate PGR reappears in patients who recover from their psychoses.

The combined effect of physiological and emotional stimuli on the reaction of the organism is illustrated by the following observations. If drugs are given to diminish sweat secretion (atropine), the PGR is diminished or abolished. In conditions like hyperthyroidism accompanied by excessive sweating, the skin resistance is lowered.

Electroencephalography—Sleep. Electroencephalography is the recording of currents that are obtainable through electrodes attached to the skin of the skull or to the brain. They are

produced by electric activities of the brain. (Berger, 1929.) Thus it is possible, although in a limited way as yet, to record changes, correlated with psychological phenomena, in the nervous system itself instead of merely in the peripheral organs such as blood vessels or stomach.

Dreams indicate that during sleep introspective experiences continue, but self-criticism and repression are diminished. Thus impulses, attitudes, conflicts, emotions, and memories become revealed which are kept from awareness in the waking state. The psychosomatics of sleep is as yet little known. There is more blood in the brain, the temperature of the body is lower, the muscles are relaxed, breathing is periodic, and there is an increase of carbon dioxide in the blood. The depth of sleep is paralleled by the changes in electric phenomena produced by the brain.

A subject with electrodes attached to the scalp is put in a situation conducive to sleep and the electrical potentials produced by the active cells of the cerebral cortex are recorded on a continuous moving paper for several hours, while the subject goes through various phases of sleep. A large proportion of normal persons show regular ten per second waves (α waves) when fully awake but with eyes closed. When drowsiness or the "floating state" sets in, the ten per second rhythm becomes less regular and as light sleep comes on the waves may group themselves into spindles with spaces between, where waves are small or absent. As sleep deepens, some slower waves appear (six per second), and in really deep sleep long, slow waves replace the faster rhythm. In the deepest sleep, even these tend to disappear and the electroencephalogram is almost a base line with a few small waves. Sudden awakening immediately brings back the normal rapid rhythm associated with alertness.

Subjects in sleep are still able to discriminate between stimuli. It has long been observed that a mother will wake at the slightest cry of her child when much louder noises do not seem to disturb her. In harmony with this, loud automobile noises outside the house had no effect upon the electroencephalogram of a sleeper, while a slight noise in his room, especially the slight snap made by pressing an electric switch, would start a change in the sleep waves toward the waking type.

Hypnotic Blindness. In normal waking state, ten per second waves are usually present if the subject has his eyes closed. They disappear if he opens his eyes in the light. The subject of the experiments to be reported was a patient who had been frequently brought under hypnotic suggestion for therapeutic purposes. When he was hypnotized, he still showed his normal waking (electroencephalographic) record, with no indications of the changes characteristic of sleep. The hypnotist suggested to the subject that he was blind and could not see. Although the eyelids of the subject were held open by adhesive tape and the room was illuminated, the alpha waves appeared in the electrical record. The hypnotist suggested that the patient had regained his vision; the alpha waves promptly disappeared. Sight and blindness were suggested alternately 16 times, and each time the EEG showed a corresponding change. The changes were essentially the same as if the subject had actually opened and closed his eyes. (Loomis, Harvey, Hobart, and Davis, 1936.)

Epilepsy, Psychopathic Personality, Passive Dependent Trends. In all of the applications mentioned, the EEG was correlated with transient psychological phenomena. In other applications, however, some permanent features in the EEG have been related to the tendency of the individual organism to react in certain pathological ways. Normal EEG's exhibit either eight to twelve per second (α waves) or 16 to 30 per second (β waves) rhythm. In epilepsy, the EEG may show bursts of "spike and dome" or of low frequency high amplitude waves between overt attacks or before attacks have yet occurred. More difficult to evaluate are some findings in behavior disorders in children (Jasper, Solomon, and Bradley, 1938), and "psychopathic personality." The latter condition is characterized by superficial emotional attachment, impulsive behavior, lack of sense of responsibility, and often aggressive or criminal behavior. About fifty per cent of patients in these groups show slow (five to seven per second) waves scattered through the EEG. (Hill and Watterson, 1942; Simons and Diethelm, 1946.)

Although open to debate as yet, a further development in the methodology of utilizing the EEG in psychosomatic investigations is illustrated by the following:

The α index expresses the percentage of α rhythm in, let us say, a two minute run of

EEG. This is fairly constant for a given individual. The term "dominant" α rhythm was applied to runs in which 75 to 100 per cent of the waves are of the α type. By evaluating the subject's dreams as indications of his bent for "activity" or "passivity" a correlation could be established between high α index and "passivity" on the one hand, and low α index and "activity" on the other (Saul and Davis, 1937). It was found that 71 per cent of 100 patients with peptic ulcers and 60 per cent of 45 patients with bronchial asthma (see both later) exhibited "dominant" α indices. The incidence of dominant α index in unselected "normals" is 20 per cent. In both the above conditions, reactions to frustrated dependency longings play an important role in the dynamics of the illness. (Rubin, Bowman, and Moses, 1944.)

Hypnotic Experiment. Experiments with hypnosis are particularly instructive, because they can produce alterations in body function of such types as are observed in sick individuals.

The subject is asked to fix an object with his eyes while the experimenter keeps repeating, "Your eyelids are heavy and droop"; "You breathe calmly and deeply"; "You are relaxing"; "You are falling asleep." Some subjects go into a sleep-like state in a few minutes, whereas others do so only after several prolonged trials. Perhaps only about 10 per cent of the population responds easily. Deep hypnotic trance is usually followed by spontaneous amnesia. (Messer, 1966; Braid, 1843.)

Pulse Rate and Metabolism; Unconscious Processes. Subjects were hypnotized, their pulse rate and metabolism recorded. After a control period, individually meaningful harrowing experiences were suggested to them while pulse rate and metabolism were being recorded; e.g., a woman who was much attached to her mother was told that she and her mother were separated in a forest during a storm. There was a rise of about 27 in the pulse rate per minute and of approximately 20 per cent in the metabolism. She was then told that after waking from the trance she would forget the experience, but that her reaction would be revived when the experimenter took a handkerchief out of his pocket. In the post-hypnotic waking state, whenever the experimenter took the handkerchief out of his pocket her metabolism and pulse rate rose without conscious anxiety and without her knowing why (Deutsch and Kauf,

1923). Rise during fear was confirmed by other investigators, who also found that depressive, elated, or irritable moods, induced in hypnosis, were not accompanied by a rise in the basal metabolic rate. (Whitehorn, Lundhold, and Gardner, 1929.)

Catalepsy. The production of cataleptic rigidity in a somnambulistic state is a commonly observed phenomenon. The subject is told that he will hold his arm in a certain position, and he then proceeds to do this very long beyond the possible limit of waking fatigue.

Paralysis and Aphonia; Circulatory Changes in the Skin. Hysterical phenomena such as paralysis of an extremity or aphonia (ability to talk only in whispers in the absence of structural damage to the vocal cords or the motor nerves) can be made to disappear and reappear in hypnosis. This was first done by Charcot (1890). These experiments involved muscles with voluntary innervation. Even more dramatic were his experiments with hypnotic influence on autonomic functions such as circulation of the hand. Dr. Levillain, of Paris, records a case where Charcot is said to have produced the *acédie bleue des hystériques* by suggestion. The subject was told that her hand would swell, become blue, and turn cold. The hand increased to nearly double its former volume and presented all the appearance of "blue edema"; its temperature fell 3° C. lower than the rest of the body. Suggestion quickly caused the symptoms to disappear.

Skin Blisters. The subject is put into a deep hypnotic state. His skin is then touched with an object, e.g., a pencil, and the suggestion is given that the object is a red hot iron. There is an immediate circulatory change and some hours or a day later a blister forms at the site where the burn was suggested. This blister, on microscopic examination, shows the same histological changes as a blister actually caused by a burn. The course of healing is also the same. (Dowswald and Kreibich, 1906.) Such experiments are not successful with every subject who is put in a deep hypnotic state.

Emotional Stress and Lowered Resistance to Infection. Several patients suffered from periodic attacks of small blisters around the mouth (*herpes labialis*). It was found that these attacks followed reactions to situations of stress. These patients were hypnotized when they were free from blisters; and severe, emotionally

traumatic events (for example, death of the fiancé) were discussed with them. After the trance the patients always developed blisters.

The experiment was carried further. The contents of the blisters were transferred to the eye of a rabbit. The fact that the rabbit developed small blisters and then ulcers on the cornea proved that the contents of the blisters contained germs. (The germs that are responsible for *herpes labialis* have not yet been identified, but the infectious nature of the condition can be proved in this way.) (Heilig and Hoff, 1928.)

Past Experience and Psychosomatic Illness. In some subjects the following experiment is possible. The subject is told in deep hypnotic state that it is his fifth or sixth or third or tenth birthday. In many subjects then, it can be observed that their reactions and their behavior are largely commensurate with their development at the age stated. Thus the infantile reactions, walking on all fours, taking objects into the mouth, and sucking their thumbs, appear.

In some subjects an even more unique and circumscribed preservation of memory of events can be demonstrated. Let it be assumed that it is known that when the subject was five years old, he had severe attacks of hives (urticaria). He is given the suggestion that he is six years old. No change occurs in the skin. Then he is given the suggestion that he is five years old. The subject then complains of itching and soon hives appear on the skin. He is then told that he is four years old; the hives disappear. He is again told that he is five years old and the hives reappear.

LARGE-SCALE AND RAPID METHODS OF SURVEY

Three methods have evolved for large-scale and usually rapid survey of psychosomatic manifestations in sample populations or in studying reaction patterns in individuals with certain types of somatic disorders.

(1) *Brief Psychiatric Interview.* The interview covers in three to fifteen minutes most important personality and psychosomatic disturbances. It involves indispensable questions such as, "Have you ever had a nervous breakdown?" "Do you have bad stomach trouble?" "Were you ever badly depressed?" "Did you ever have fits or convulsions?" At the same time, as much freedom and informality is al

lowed as compatible with the brief period allotted to the interview. The final results are then classified on the basis of dominant symptomatology and further on the basis of presence and intensity of symptoms. An illustration of the results with such a method is given on 450 unselected admissions to medical and surgical hospital wards. Forty-five or 10 per cent were appraised as having severe personality disturbances, and ninety or 20 per cent as having moderately severe personality disturbances. (Mittelman, Weider, Brodman, Wechsler and Wolff, 1945.)

(2) *Rapid Test Procedures.* The Cornell Index, in its short form, consists of 62 questions. Half of them concern bodily complaints. Some of the questions aim at ascertaining the presence or absence of very severe symptoms, such as peptic ulcer or convulsions. Other questions aim at milder symptoms, such as dizziness or

palpitation. The Cornell Word Form is a less direct method, aiming at the same goal. It consists of a series of stimulus words, each followed by two words from which the subject is asked to choose the one that "goes better" with the stimulus word, e.g., "HEAD: mind, hurt." The choice "hurt" suggests the symptom of headache. Either of these test blanks can be completed by the average literate person in five minutes, and it can be scored in half a minute. The results can be used either qualitatively or quantitatively. In the latter case a certain number (or more) of "symptomatic" replies is taken as indication of personality or psychosomatic disturbance.

Both of these tests have been validated against psychiatric interviews. (Weider, Mittelman, Brodman, Wechsler, and Wolff, 1945.) The following table illustrates the results found in validating the Cornell Index:

Incidence of "Stop Questions" * Among the General Selectee Population, Those Accepted or Rejected by the Interview Method in New York and Boston, and Those Discharged by the Army and Navy Because of Performance and Neuropsychiatric Disability.

	"Stop Question"	General Selectee Population 1,000 cases	Accepted by Interview Method at Induction 887 cases	Rejected by Interview Method at Induction 113 cases	Discharged by Army and Navy Because of Performance and Neuropsychiatric Disability 282 cases
	No.	%	%	%	%
Alcoholism	5	0.7	0.1	5.7	10.4
Headache	10	8.7	5.3	35.4	48.7
Fits	15	1.8	0.8	9.7	18.0
Drug Addiction	20	0.8	0.7	1.4	3.8
Stomach	30	7.5	5.9	20.4	19.3
Enuresis	40	3.0	0.8	11.0	7.3
Stay in Mental Hospital	45	0.7	0.2	4.4	11.7
Sleep Walking	50	1.0	0.6	4.4	5.5
Severe Diarrhea	55	2.1	1.4	8.0	9.3
Nervous Breakdown	59	0.7	0.2	4.4	33.9
Peptic "Ulcer"	60	0.4	0.2	1.4	8.3

* "Stop Question" refers to those questions which aim at severe symptoms.

(3) *Study of Standardized Psychological and Behavioral Items.* In this method of procedure, items like educational level, kind or severe parents, overt irritability or calmness are routinely checked and evaluated in one or two interviews. The relative frequency of various types of items

is then compared as it occurs in groups of patients with various disorders. As an illustration the following findings are given: Patients who are admitted to the hospital with fractures have been found to have in general a lower educational level than patients who were ad-

mitted with disease of the coronary artery of the heart. Secondly, it has been found that fracture patients in a larger percentage than coronary patients do not finish the school period that they have undertaken. (Dunbar, 1943.)

These results imply varying personality traits for patients who develop varying illnesses. Many individuals try to solve conflicts through getting out of the situation or through impulsive action. Such action may result in fracture. It may even represent a suicidal attempt, in that the patient unwittingly exposes himself to an accident. Other individuals try to solve their conflicts through insistent and consistent pursuit of goals. They use their aggressions, which they keep under control, for the purpose of getting themselves accepted through achievement and by coming up to expectations. Patients with coronary disease show a tendency in this direction. The strain that this behavior puts on the vascular system and the heart contributes to the causation of the ultimate illness.

The large-scale methods establish certain common features presented by a majority of a group of subjects and in this sense are essentially statistical. The particular individual may be totally different in his reactions from the general trend. Some accident prone patients not only have finished college but are superior in their achievements and follow their goals with dogged consistence. Further, accidents resulting in fractures may be due to the patient's fault or to somebody else's fault. Large-scale surveys identify mainly trends that are significant enough to show in the final results in spite of all the variables encountered.

Sexual and Ethnic Differences in the Incidence of Psychosomatic Disorders. A review of the incidence of perforated ulcer at the New York Hospital from 1880 to 1900 revealed that women had perforated ulcer at least as commonly as men, i.e., 6:7. (Mittelman and Wolff, 1940.) All perforations in these patients were visualized either at operation or autopsy (all autopsies from 1880 to 1891). Beginning in the period of 1901 through 1906, the ratio of males to females changed. The following figures were found for the years 1901 to 1939:

	Males	Females	Ratio
1901-1906 (5 years)	10	4	2½:1
1907-1914 (7 years)	55	9	6:1
1915-1930 (15 years)	260	16	16:1
1931-1939 (8 years)	36	3	12:1

Similar changes have taken place in Germany, France, Scandinavia and the English speaking countries. (Jennings, 1940.) Such change may have been due to the shift in the self-esteem-dependency conflict in the relationship between men and women as a result of the historic, economic, and cultural events.

Coronary disease of the heart is more common among men than among women. Arterial hypertension is rare among the Chinese. The explanation may be that both of these illnesses are favored by hard-driving work. The incidence of exophthalmic goitre on the other hand is higher among women (5:1), due either to endocrine differences or to women's greater demand for dependency and the resultant fear of, and resentment at the thought of, frustration and abandonment.

THE RORSCHACH TEST

The Rorschach test consists of ten standardized inkblots. The subject is asked to tell what he sees in them. The mode of response to the blots tends to be characteristic of the deep personality configuration of the person making the response. (Rorschach, 1921.) The value of the test in psychosomatics is illustrated by the following examples: Patients with an organic lesion of the brain tend to see very few things in the blots and to base their responses largely on shape rather than color or a sense of movement. They are typically perplexed by the task although they make an effort to comply. They tend to repeat the same answer regardless of changes in the contours of the blots. The reactions typical of such patients have been so well studied that it is often possible to make a diagnosis from the Rorschach in advance of conclusive neurological signs. (Piotrowski, Harrower, 1940.)

The test reveals characteristic personality types for various psychosomatic conditions respectively, e.g., rheumatic disease, hypertensive cardiovascular disease, coronary occlusion, fracture (accident proneness), migraine, etc. (Kemp, 1943; Ross, 1945). Such differentiation depends not upon the appearance of special signs for each condition, but rather upon indications of the whole personality complex in the test results. Patients with rheumatic disease are often seen to be passive, masochistic, infantile individuals. Hypertensive patients are characteristically more ambitious for power, with more

conscious hostility and a constant conflict between aggression and passive dependency needs. Patients suffering from migraine show persistent effort toward success, perfectionism, inflexibility, conventionality, and intolerance, with difficulty in sexual adjustment. Fracture patients must be subdivided into three groups: the "introverse" who tend to seek satisfaction within their own emotional and imaginative experience; the "extratensive," seeking satisfaction through traffic with the outside world; and the "constricted," who attempt to repress all spontaneity of feeling and experience. All of the groups show a strong effort to compromise between passivity and aggression, with emphasis on self-determination, independence of authority and on day-to-day pleasures.

ANIMAL EXPERIMENTS

Transient Reactions (Acute Experiment). The multiplicity of psychosomatic reactions is particularly well illustrated in the following experiments. A cat was tied to the experimental table and the pulse rate, blood pressure, presence of sugar in the urine, and the motility of the gastrointestinal tract, as well as its circulation as judged by the color of the guts while exposed, were observed. Then a barking dog was brought into the laboratory. As a result of this, the heart beat of the cat became rapid, the blood pressure rose, the gastrointestinal activity diminished, the color of the guts became paler, and sugar appeared in the urine. (Cannon, 1915.) If the sympathetic nerve supply was severed, the reactions still occurred though less intensely. If the sympathetic nerve supply to the adrenal gland was severed, the reaction did not occur. Thus the conclusion was warranted that this reaction was mediated through the sympathetic nervous system as well as through the outpouring of the adrenal secretion. The experiment was more successful with female cats than with male cats. The reason was that the female cats, being less excitable, were able to relax while tied to the experimental table, whereas the male cats were in a continuous state of low rage, and therefore the introduction of the barking dog did not have such dramatic effect. This observation about the complex effect of the sex gland and the emotional reactivity of the organism is in harmony with the general observation of the excitability of stallions and bulls. The organismic and en-

vironmental approach of Cannon also is illustrated by his constructions based on this experimental observation. His assumption is that these changes represent measures on the part of the organism to deal with an emergency situation. The increased blood supply to the muscles, together with the mobilization of the sugar, the increase in the heart rate, diminutions in the activity of the gastrointestinal tract, all prepare the animal for his struggle and enable him to fight better.

Method of Conditioning. A dog, who was operated on so that the excretory duct of the parotid gland opens on his cheek, stands on a platform with slings under his fore- and hind-legs which prevent him from moving away. The receiving tube is gummed to his cheek over the opening of the duct. The experimenter lets a metronome sound, say at 130 ticks per minute, for just a few seconds and then food is presented. The time during which the metronome ticks (before food) is gradually increased to ten, fifteen, twenty, or thirty seconds. After ten or fifteen trials, the conditioned response essentially a psychosomatic reaction is well established, in that saliva is secreted during the beating of the metronome, the conditioned stimulus, before food is presented. The response includes the motor reaction of turning toward the source of food and incipient chewing movements. If the metronome is now made to beat at ninety ticks per minute, saliva is secreted. If, however, in further experiments, the 130 rhythm is regularly followed by food, the ninety rhythm is not, the animal finally differentiates between the two and secretion occurs only on the 130 rhythm. (Pavlov, 1900.)

In his formulations of his fundamental findings, Pavlov took mainly the coupling of the conditioning stimulus and the response into consideration. "Under suitable conditions, a new connection must be formed at the very first occurrence of the stimulus excitation, and this becomes strengthened by every repetition." He further formulated his results in terms of two opposite factors, excitation (resulting in secretion) and inhibition (cessation of secretion). He observed some other features of the conditioning experiment which he did not utilize in his formulation. He noticed that for a successful experiment the dog must be taken for a walk before the experiment, be given a drink of water, be hungry, wide awake, and alert,

free from any painful or irritating stimulus and well-adapted in advance to the laboratory, the apparatus, and the experimenter. On the basis of these additional data it can be said that the animal becomes adjusted to the new situation and reacts meaningfully to a significant stimulus. The unconditioned stimulus becomes a "signal" (Pavlov at times used this term himself) of the biologically important facts of the environment. The animal has to be hungry, otherwise the presentation of food has no meaning for him. The concept of "adjustment" has the implications of being safe, cooperative, and able to concentrate on a task.

"Experimental Neurosis." Pavlov also made the first observation on "experimental neuroses" in animals by means of the conditioning method. This topic, together with further broadening of the scope of observation will be discussed in connection with the following experiments.

The sheep or lamb selected for conditioning must at first be caught and forced into the laboratory. It is usually necessary to lift the animal on to the table and tighten the loops under the legs to prevent escape by struggling, lunging, crouching, and jumping. Within a few days or weeks, *opposition changes to willingness*. The sheep is more easily caught in the barn, stands quietly while a chain is fastened around its neck, and now it leads the experimenter from the barn to the laboratory, often tugging at its leash. Mounting the inclined platform to the table, it eats from the bucket of oats and allows the loops to be adjusted without struggling. It stands quietly when food is taken away, and even when the loops are removed from the limbs.

An electrode is bound to the sheep's foreleg near the shoulder and electric shocks of moderate intensity are applied. A few seconds before each shock, a metronome begins to tick and it keeps on till the shock arrives. As the experiment proceeds, a diffuse conditioned response, struggling, agitated breathing and heart beat, and the psychogalvanic reflex at the sound of the metronome, gives way gradually to one that is localized and precise. At the sound of the metronome, the sheep raises his head and ears, assumes a crouching position, and half flexes the leg that carries the electrode; when the shock comes, the animal flexes the leg completely, replaces it on the ground and relaxes.

The animal could be conditioned in a similar manner if the electric shock came at the tenth, fifteenth, or even at the twenty-fifth second. If, however, the interval was thirty seconds, the animal waited too long, then not long enough, before the shock came. After such experiences, the animal's behavior changed in and out of the experimental environment. Henceforth, it was restless on the platform. Even when the metronome did not beat, it kept moving its foreleg. When the metronome did beat, it fixed its foreleg with each beat. But still other changes were noted in the animal. Where it formerly went willingly to the laboratory on collar and chain, it now vigorously resisted going there and had to be placed by force on the table. It became more restless even in the pen both during the day and during the night, and tended to be withdrawn, to crouch in a corner, and to be more submissive in case of attack. Its pulse became rapid and irregular as compared with that of the normal animal. The condition in some of the animals continued for several years. Thus an enduring change was produced in the animal's total behavior combined with a psychosomatic disturbance. (Liddell, Anderson, and Parmenter, 1935.)

Such a "neurotic condition" did not occur if the sheep had to learn a simple maze where, if it could not solve the problem, it could turn its attention to other matters. If the same sheep learns to stand quietly and to restrain itself on the platform, it *has* to come to grips with the problem presented.

The concept of adjustment to the normal conditioning situation here includes also an internal change in the animal which can be described only in human terms. To quote Liddell, "It is our belief that this restraint, first imposed from without, and then imposed by the animal upon itself, is the fundamental condition favoring the development of nervous strain with resulting neurosis." It is almost as if the animal, under normal circumstances, were willing to stay finally in the experimental situation and cooperate because of the friendly support of the experimenter. Once his feeling of safety is sufficiently damaged, almost the whole world becomes threatening.

Individual animals vary in the relative ease with which they develop neuroses and in the type of neurosis manifested. In some dogs, it consists mainly of general excitement and con-

tinuous excessive secretion; in others of falling asleep, manifesting waxy-flexibility (the animal's limbs retained the position passively given), and absence of secretion. Pavlov was inclined to attribute these differences to the glandular balance of the animal. These observations prove that the animal's "constitution" or "make-up" plays an important determining role in the ultimate reaction to internal and situational stress.

GROSS OR CHEMICAL DAMAGE TO BRAIN STRUCTURES

Clinical Observations—The Frontal Lobes of the Brain. Frontal Lobectomy: A forty-year-old successful broker on the New York Stock Exchange developed a tumor of the brain. During the operation, large portions of his frontal lobes (premotor areas) were removed on both sides.

He boasted of his prowess in dancing, fighting, and sex, although his actual performance was poor. Together with that he was inclined to be facetious and euphoric. His memory for recent events was faulty. He was incapable of logically following through a topic in thinking or in conversation if this topic was in any way complicated.

On other occasions he behaved in a childish, angry, and abusive manner. He would refuse to get undressed in the evening and to wash his face in the morning. He would walk into a room where people were playing cards and would say, "You're all a lousy bunch of players. Do you want to start something?"

This patient had been a shy and quiet child, submissive to his dominant father and dependent on his mother. In general, he had been a mild and submissive individual who repressed all hostility and had been compensating for his feelings of inadequacy by a whimsical, humorous, and somewhat boastful manner. The one function that had been good was his occupational activity, which he was unable to resume after his operation. (Brickner, 1936.)

The effects of the frontal lobectomy were the complex resultants of the following processes: (1) impairment of the previously good intellectual function (memory and logic); (2) a decrease in self-criticism and self-restraint, and, as a result of this, a compensatory increase in spurious self-evaluation, in the expression of previously repressed hostility, and in childish, dependent attitudes. The functions that he re-

tained from previous periods were some ideals of achievement, a desire for the respect and praise of others, and some self-criticism.

Frontal Lobotomy. An operation has been carried out on a moderately extensive scale on patients who suffer from very severe psychopathology (mostly depression and obsessive-compulsive states). The operation consists of severing the pathways that connect both frontal lobes with the rest of the brain. The permanent effects of the operation are usually as follows: Inertia and lack of ambition, reduction in consecutive thinking, loss of what is commonly called self-consciousness, indifference to the opinions of others, satisfaction with performance even though this may be of inferior quality and quantity—these may be considered among the primary results. Euphoria, evasion, bluffing, talkativeness, facetiousness, aggressive behavior, teasing, indecent acts, inattention, poor judgment—these might be classed among the secondary results.

What is accomplished by the operation is a separation of the ability of the individual to project himself into the future and the feeling tone that accompanies this. Moreover, it is especially the inner sensations, ideas, recollections, ambitions, and disappointments, the regrets for the past and the fears for the future, that are particularly affected in this way. (Freeman and Watts, 1942.)

In a series of 74 cases, the following symptoms were most commonly produced:

Symptom	Total	Persistent	Temporary
Lack of initiative . . .	73	30	43
Euphoria	60	22	38
Procrastination	56	29	27
Laziness	52	22	30
Facetiousness	49	18	31
Tactlessness	47	43	4
Increased appetite . . .	70	50	20

The Hypothalamus. The hypothalamus is an area at the base of the brain and just above the pituitary body. It has been known for some time that this region of the brain plays an important role in vegetative innervation and in metabolism. Centers have been located which play an important role in regulating the heart rate, the heat production, urinary secretion, circulation, oxygen and sugar metabolism. In more recent years, both clinical and experimental observation indicate that the hypothala-

mus plays an important role in general emotional expression and possibly in emotional experience.

Epidemic Encephalitis (Sleeping Sickness). The most interesting observations in this condition were made on individuals who contracted the illness in childhood. After the acute phase passes, one of the characteristic symptoms is so-called hyperkinetic behavior. The individual is over-active, engaging in a variety of activities many of them destructive. This is often combined, particularly in adolescence, with the use of obscene words, excessive and uninhibited sexual behavior such as masturbation, heterosexual and homosexual activities, exhibitionism. In still severer instances there are mood changes such as hostile, sarcastic irritability, at times with depression. There may also be smearing with feces and attacks on other persons, for example in the form of dangerous biting. If such an individual dies of an intercurrent illness, e.g., pneumonia, abnormal microscopic changes are found in the region of the hypothalamus, indicating a low-grade chronic inflammation. The psychiatric disturbance is often associated with obesity, irregular menstruation, premature sexual development, and altered distribution of the hair.

Also of pertinent interest are psychiatric symptoms observed in patients with brain tumors located in this region. If the damage is in the front part of the hypothalamus, excited states with flight of ideas are at times observed. *In lesions in the posterior part, more common observations are lethargy, indifference, depression, with a tendency to assume an immobile posture and not react to the environment, as in catatonia.*

It seems likely that such pathology in the region of the hypothalamus affects the individual's physiological drives, his aggressiveness, and his reactivity. The individual reacts to the environment in terms of these altered drives. The self-criticism and guilt is not lacking here either, but the patient is unsuccessful in controlling his altered drives, and the conflict results in a defiant reenforcement of the drives. Many of the children, if placed in an institution, can be reeducated so as to function adequately even after they are returned to their home environment. This again illustrates the significance of the environment and the process of "internalization."

EXPERIMENTS ON HUMAN BEINGS

A curved insulated electrode was inserted through the nostril and embedded in the sphenoid bone (at the base of the brain), constituting the "hypothalamic" lead; "cortical" leads were also taken, from the scalp. The "hypothalamic" electrode could be used for electric stimulation with the purpose of observing the effects of, and also for obtaining encephalograms during, emotional stress. Electric stimulation through the nasal electrode caused pupillary dilatation, perspiration, and rise in blood pressure. Sometimes anxiety appeared and persisted with crying and expressions of fear for some minutes. Several patients saw their lives pass before their eyes, as has been described in drowning.

At rest, the hypothalamic waves showed a four per second rhythm, the cortical waves, a ten per second rhythm. Following the electric stimulation through the "hypothalamic" electrode, the electric waves obtained from the hypothalamus, as well as those obtained from the cortex, showed alterations. At times they became synchronous. Similar alterations were observed when strong emotions were evoked in a patient by telling him that masturbation had "irreparably damaged him. The cortical and hypothalamic waves then became irregular and partly synchronous, and giant waves and plateaus with frequent cusps appeared." (Grinkier and Serota, 1938.)

EXPERIMENTAL INVESTIGATION ON ANIMALS

Frontal Lobectomized Animal. The frontal lobectomized chimpanzee is distinguished from the normal animal by his restlessness and distractibility and "by a rather fatuous equanimity of spirit which one encounters in a good-natured drunkard, but never in a normal chimpanzee." (Fulton, 1939.) The intellectual performance, including memory, suffers, as indicated by the animal's performance in the following tests.

In the more complex form of the stick-and-platform test, the animal has to use shorter sticks to gather in longer sticks beyond his reach, finally reaching the banana with the longest stick. In another complicated test, sticks of varying lengths are placed on two platforms. In order to get the banana, the chimpanzee has

to carry the sticks from one platform to the other. The normal chimpanzee is able to do this task successfully; but if the premotor areas in both sides are removed, the animal cannot do this.

The delayed reaction test is as follows: There are two cups in the cage, separated from the animal by the bars and a glass door. Food is placed under one of the cups. After a certain length of time the animal is permitted to reach for the food. In order to choose correctly he has to remember under which cup the food was placed. The normal chimpanzee can do this task correctly after intervals of as long as five minutes. After bilateral frontal lobectomy, the chimpanzee is unable to do it after an interval of five seconds.

This test can be made more complicated by lowering an opaque screen after the food is put under one of the cups. The chimpanzee, of course, cannot see the cups until the screen is raised. At times, even normal animals become emotionally disturbed and fail in this form of the test. Thus an adolescent female, affectionate, cooperative, and eager to work in the problem situations, became greatly upset whenever she made an error in the delayed reaction test. In these circumstances she flew into a temper tantrum, during which she rolled on the floor, beat the grate, defecated and urinated, and showed signs of diffuse sympathetic discharge. She finally refused to go into the problem cage. After the removal of both frontal areas, a profound change occurred in this animal. She ran eagerly into the experimental cage, did not get excited when the opaque screen was lowered, and never showed any emotional disturbance no matter how many times she made a mistake. "It was as if the animal had joined the happiness cult of the elder Micheaux and had placed its burdens on the Lord. Objectively the animal failed in the test even with only the glass door in operation." (Jacobsen, 1935.)

Ablation Experiments and Stimulation of the Hypothalamus. If the brain is removed above the hypothalamus in cats, the animals easily exhibit spasms of ragelike behavior when disturbed. At times even the rubbing of the cat's skin is sufficient to precipitate this behavior. The manifestations are arching of the back, clawing, lashing with the tail, snarling, tongue movement, and violent struggling if held, or the animal dashes itself against available ob-

jects. Together with this there is increased breathing, salivation, widening of the pupils, and pyloerection. If the cat is operated on one side and the brain anterior to the hypothalamus is removed, the cat will exhibit ragelike reaction to being stroked on the operated side, and will remain a friendly, purring cat if stroked on the other side. (Bard, 1928.)

Very similar behavior is observed in the cat with electric stimulation of the hypothalamus through implanted bipolar needle electrodes in the unanesthetized, freely moving cat. The animal begins to retract its ears, crouch, growl, raise its back and lash its tail, and to show a crescendo of the following typical sympathetic and motor reactions: hyperpnocia, salivation, mydriasis with widened palpebrae, pyloerection, biting and striking movements with claws unsheathed, and, finally, precipitate running as though in blind attempts to escape. (Ransom, 1934; Masserman, 1938.)

It is to be noted that the bilaterally frontal lobectomized chimpanzee is much closer to the bilaterally frontal lobectomized or lobotomized human than the hypothalamic animal is to patients with lesions in the hypothalamic regions. This is not surprising, because there are obvious differences in anatomical disturbance in patients with lesions of the hypothalamus and the animal whose hypothalamus is stimulated or in whom the rest of the brain is removed. Nevertheless, there is some similarity between the aggressive, hostile, hyperkinetic post-encephalitic patient and the rage reaction of the animal. Some investigators emphasize that the hypothalamus is not a center of emotional "experience," but one of the important effector relay stations of emotional expression. (Masserman, 1941.)

THE AUTONOMIC NERVOUS SYSTEM

The function of any organ in the body may be of significance for psychosomatics in the broadest sense. In the customary more limited sense, however—normal or pathological changes in bodily function occurring during passing or sustained emotional reaction—the function of the autonomic nervous system is of the most universal significance. It is called "autonomic" because it is not under voluntary control, it has "autonomy." It is motor in its function (it carries centrifugal impulses) and has two main divisions: the "sympathetic" and "parasympa-

thetic." Roughly these two divisions differ in their (1) anatomy, (2) function, (3) reaction to drugs, and (4) chemistry of activity.

Anatomically the "sympathetic" part is also called "thoraco-lumbar outflow" because the fibers leave the spinal cord in the thoracic and lumbar sections. The "parasympathetic" is called "craniosacral outflow" because its fibers leave the central nervous system with the cranial nerves or from the sacral section of the spinal cord. Functionally the two systems are largely antagonistic. Stimulation of the sympathetic causes: dilation of the pupil; protrusion of the eyeball; secretion of sweat; erection of hair; vasoconstriction of most arteries; acceleration of the heart; dilatation of the bronchi; inhibition of intestinal peristalsis with closure of the pyloric sphincters. Stimulation of the parasympathetic causes: slowing of the heart; constriction of the bronchi; contraction of the stomach and intestine with relaxation of their sphincters; secretion in the stomach and pancreas; constriction of the pupils; and in general vasodilatation of most arteries.

As regards reaction to drugs in general, and chemistry of activity adrenin stimulates the sympathetic, ergatamine tartarate inhibits it; atropin inhibits the parasympathetic, pilocarpin stimulates it. The activity of the sympathetic is mediated from the nerve ending to the executive apparatus by the production of adrenin—that of parasympathetic by the production of acetylcholin.

The anatomical differentiation between the two systems, however, does not entirely parallel the chemical differentiation. Thus the sweat glands are supplied by the sympathetic (lumbosacral outflow), yet they are cholinergic in their response.

Both systems have a peripheral cell system, a next higher representation in the spinal cord or brainstem, next higher in the diencephalon (hypothalamus), and, as recent investigations have shown, in the frontal lobes.

The sympathetic system has a greater tendency toward diffuse, the parasympathetic toward circumscribed, reaction. Normal function requires a balance between the two systems. Although signs of over-reactivity of one of the systems usually predominate, in most patients symptoms arising from both systems are present.

Experimental investigations indicate that in

acute emotional reactions, there is a rise in the blood of both cholinergic and adrenergic substances. The rise of the adrenergic substance was proved by Cannon (1915). The rise in the cholinergic substance was shown recently by two experiments. The nerve impulse to the skeletal muscles is mediated by acetylcholin. The facial nerves of monkeys were severed. During the period when the neuromyal (nerve-muscle) junction became over-sensitive to stimulation, the monkey's face twitched whenever he was frightened. This proved the presence of an excess amount of cholinergic substance in the blood during excitement. (Bender, 1938.) Also, the excised intestinal loop of the rabbit continues its tone and rhythmic contractions if placed in Ringer solution. If the blood of anxious depressed patients was added to the solution, the tone increased (cholinergic effect), but the contractions became irregular and of lesser amplitude (adrenergic effect). (Milhorat, Small, Doty, and Bartels, 1943.)

THE THYROID HORMONE AND PSYCHOLOGICAL FUNCTIONS

Adult Myxedema. In this condition the adult person exhibits the following symptoms: His skin becomes dry, sweating is diminished, there is a swelling of the skin that does not retain the mark of the finger-pressure, and the pulse is slow (ca. fifty per minute). Together with this, there is a considerable slowing down of reactions and decline in the intelligence. All these manifestations are accompanied by a striking drop in the basal metabolism of the body (—30 to —40 per cent). If such an individual is given adequate amounts of thyroid substance, all the described symptoms disappear, and he regains his previous normal intelligence and reactivity. If most of the thyroid gland is removed in an operation on the adult, identical symptoms arise as in myxedema. (Kocher, 1883.) They are likewise corrected by the administration of thyroid.

Cretinism. In this condition the individual is born with an insufficiently functioning thyroid gland. If the individual is not treated, he exhibits a stunted and disproportionate growth, a large tongue, and all the other symptoms described under adult myxedema but in greater severity. The intelligence is that of either the idiot or the imbecile, and the individual is unable to acquire relatively elementary social hab-

its of cleanliness and adequate regulation of excretory functions. If the condition is recognized early in infancy and the individual receives adequate amounts of thyroid throughout life, the majority of such patients develop normally. If the treatment is started too late, or if the condition was of long duration *in utero*, thyroid substance will not be effective in repairing damage to previous development.

Excessive Thyroid Function. If normal individuals take large enough amounts of thyroid substance, the following phenomena can be observed: There is an increase in pulse rate, excessive perspiration, trembling of the hands, general restlessness with inability to relax, increased irritability, emotional instability in the sense of temper outbursts, easier crying and laughing, and over-talkativeness. This is accompanied by a rise in the basal metabolism (ca. 25 to 50 per cent). The severity of these symptoms, including loss of weight, partly depends on the amount of thyroid taken. If the thyroid intake is discontinued, the symptoms disappear.

The observations mentioned illustrate the fact that metabolic changes in the nervous system, namely increased or decreased oxidation correlated with various levels of thyroid hormone, result in alterations of intellect and emotional reactivity.

The changes described, as previously mentioned, are primary correlates of the altered physiochemical function. The complexity of reactions, however, is evidenced by the following additional observations: The adult patient suffering from myxedema often has strong feelings of inadequacy. He realizes the drop in the level of his performance and his inability to live up to his individual and social ideals. This is not a direct effect of the lack of thyroid substance. As a further reaction in relatively milder deficiencies, the patient may manifest increased irritability, representing a defensive hostile reaction to the feeling of inadequacy; or emotional depression may dominate the picture if the individual evaluates the deficiencies of function as a sign of worthlessness, irreplaceable lack, and deformity.

Patients with excessive thyroid substance are apt to feel guilty and self-condemnatory because of the aggressive, irritable, hostile outbursts and feel ashamed because of crying. They are also apt to feel anxious because of their inability to control their reactions.

EFFECTS OF LOW OXYGEN ATMOSPHERES

Seventeen medical students who breathed an atmosphere of 13 per cent oxygen (corresponding to an altitude of 12,400 feet) for three hours revealed marked changes in affective behavior, with impairment of emotional control; in 59 per cent elation and flightiness, terminating in lethargy, and in 41 per cent mental dullness from the beginning.

Psychoneurotic patients after inhalation of the low oxygen mixture revealed an even more marked lack of emotional restraint, with feelings of exaggerated self-esteem and sexual pre-occupations. Their mood ultimately changed from that resembling a hypomanic state to dullness and lethargy. Those patients (four of nine) who did not show elation at the start were dull and lethargic from the beginning. (McFarland, Barach, and Kagan, 1940.)

Forty college students with careful personality studies, including Rorschach test, were exposed to 9.3 per cent oxygen (corresponding to an altitude of 18,500 feet) for about one hour. The following statistically significant relationship was found between tolerance for low oxygen and personality types without overt psychoneurosis: Individuals who are rigid, anxious, not very dependent on themselves and inhibited in their responses react poorly to the high altitude situation. Individuals who are outgoing but do not have sufficient inner balance also experience difficulties, although not to the same degree as the highly inhibited group. Individuals well integrated with respect to the use of their inner resources and responsive to external stimulation react best of all. (Hertzman, Or-lansky, and Seitz, 1944.)

Résumé and Comment. On the basis of the observations on patients with bilateral frontal lobectomy, patients with pathology in the hypothalamic region, and operated animals, it can be concluded that these parts of the brain play a significant role in the intellectual, physiological, and emotional experiences of the individual. Further, it can be said that, in case of damage in these regions, and similarly in metabolic disturbances of the brain cells, the ensuing psychopathology is a complex resultant of primary alterations in the functions of the individual and the reactions of the total personality to these alterations. The reactivity changes with the environmental setting.

These observations do not elucidate the nature of the physiological functional pattern in individuals with psychogenic disturbances. They merely state that in case of removal of, or visible damage to certain brain structures, certain types of personality disturbances arise. Similarly, the discovery that the nerve cells in the central gyrus are indispensable for adequate movement and control of the skeletal musculature does not describe the neuro-chemical patterns that occur in voluntary movement, and even less do they describe the variations in these patterns and their interrelations with other patterns if the movements are purposeful, if they have a background of fear or resentment or sympathy.

SPECIAL SYNDROMES

In the preceding, general psychosomatic methods, concepts, and principles had been presented. In the following, psychosomatic syndromes will be discussed which frequently dominate the picture in individual patients. The following general remarks apply to the special syndromes:

(1) Patients usually present a variety of psychosomatic disturbances in which one symptom or syndrome predominates. At other times, there are several that predominate. The patient may have both asthma and peptic ulcers. Thus a discussion of various syndromes is done on the basis of a special focus.

(2) In explanations why an individual has a special kind of psychosomatic disturbance, the following observations and assumptions have become prevalent: (a) The individual's bodily tendencies, both constitution or incidental illness, determine the predominant syndrome in reactions to life situations. There is evidence for this assumption. Some psychosomatic disturbances, like allergy (asthma, hives, dermatitis) or hypertension, show a familial incidence, and allergic symptoms may start in early infancy. Nevertheless, psychotherapy in adulthood may relieve the patient of his symptoms. A gastrointestinal upset may first occur as a result of dietary indiscretion but may continue as a result of, or may recur regularly during periods of stress.

(b) Characteristic personality and conflicts determine the occurrence of special psychosomatic syndromes. There is evidence for this assumption also. Patients with arterial hyper-

tension commonly are well controlled, persistent individuals with repressed conflict over aggression directed towards persons in authority, together with guilt and fear of abandonment.

Nevertheless, one often finds patients with constitutional types, personalities, and focal conflicts different from those commonly encountered in the psychosomatic ailment in question. Further, it may depend on the special focus of the investigator which aspects of the total complexity of attitudes and reactions of the patient he singles out for the psychosomatic correlation. These problems will be illustrated on alterations in finger temperature as observed in a patient in the course of psychoanalytic treatment. (Mittelmann and Wolff, 1943.)

In the course of the observations, she developed, in response to a disappointing remark of her husband, a depressive (psychoneurotic) reaction, which reached its peak on the fourth day and lasted one week in all. The patient's reactions during this period of observation included feelings of rejection, first by her husband, then by the analyst, of being deprived and humiliated. Out of these feelings arose resentment, very soon repressed because of feelings of guilt, fear of complete abandonment, and frustration. The resentment included the unconscious desire to inflict genital injury, and the feeling of being abandoned included memories of parental rejection and sibling rivalry. The depression was resolved in the fifth interview through a feeling of being forgiven by the analyst and by her husband for her resentment and, as a token of that, of being accepted completely, taken care of, and sexually gratified. In four analytic interviews, the finger temperature fell concomitantly with depression, resentment, and particularly anxiety. In the fifth, the finger temperature rose concomitantly with the consciously experienced sexual excitement.

These observations illustrate the complexity of findings even in a single individual. Cold extremities were one of this patient's complaints. Her main complaint was depression, but along with it she had the complaints of fatigue, frequency of urination, and headaches. The dominant psychological pattern in correlation with fall of the finger temperature appeared to be anxiety superimposed on depression and conflicts about aggressive and sexual use of the extremities; relaxation, feeling of security, being forgiven, and sexual excitement in correla-

tion with rise in finger temperature. This patient's personality was characterized by superior intellect, persistent goals and ideals, desire for emotional closeness, and strong control over emotions. But cold extremities can also be found in shy, self-effacing individuals without strong ideals and without strong control of emotions, as well as in aggressive but anxious persons. Their emotional reaction patterns may differ in relative accent on guilt, anxiety, aggression, sexual conflict, dependency needs, and fear of abandonment—reactions observed in nearly all patients with psychopathology. We may thus conclude that in specific syndromes, characteristic personality types and emotional reaction patterns are found to predominate without exclusive uniformity.

The patient's symptoms and the results of psychosomatic experiments concern the same phenomena in conditions like cold extremities. In other conditions there is still a gap between the two types of data. Asthmatic attacks and the experimental results, i.e., alterations in the respiratory curves during stress, represent related but not identical phenomena.

In the following, these predominant personality types and conflict constellations will be presented together with the experimental evidence available for the demonstration of psychosomatic correlations.

Reactions in Which Attacks of Fear and Those in Which Obsessive Thoughts and Compulsive Acts or Fatigue Predominate. The physiological accompaniments of "anxiety attacks" have been discussed earlier (difficulty in breathing, palpitation, diarrhea, trembling, "lump in the throat," etc.). "Compulsive-obsessive states" are often accompanied by less striking physiological disturbances, e.g., cold and clammy extremities, constipation, and tremor of the hand. In "neurasthenia" the main complaints are fatigue and often, constipation. (See also "Hypoglycemia.")

Reactions in Which Impairment of Function Without Gross Structural Pathology Predominates. (Conversion Hysteria). There are several syndromes that fall under this heading. They are all characterized by severe impairment of function without gross organic pathology. The symptoms may be blindness, deafness, paralysis or spasm of one of the extremities, pain in the back, inability to stand or walk (astasia-abasia), loss of voice so that the subject is able to speak

only in a whisper, or anesthesia or analgesia (loss of sensation of touch and pain) in some parts of the body. There are two personality types that are encountered with this type of illness: One is emotionally labile with mood swings and easy crying; the other is serene, showing no alarm about the symptom. Charcot (1890) referred to this as *belle indifférence* (beautiful indifference). Psychodynamically, each of these symptoms represents an attempt at solving a conflict by eliminating a function, or preventing it as in spasm, in order to escape danger. The organ particularly affected usually has a symbolic meaning. Thus the paralysis of the hand is a way of preventing carrying out a murder which the patient unconsciously desires or a sexual act which is forbidden. In the latter instance, the organ affected unconsciously may represent the sexual organ. Treatment is psychotherapy.

Experimental Investigations. It has been mentioned previously that (1) the symptoms can be made to appear and disappear by hypnotic command. (2) The electroencephalogram changes with hypnotic appearance and disappearance of suggested blindness.

Reactions in Which General or Localized Disturbances of Muscle Tone and Status Predominate. Increase in muscle tension, tremor (trembling), and waxy-flexibility occur as concomitant symptoms with more serious psychological manifestations. Generalized rigidity of the muscles similar to the one observed in illnesses affecting the basal ganglia of the brain (extrapyramidal system), and sudden relaxation of the musculature of the body leading to an extreme weakness and collapse, however, can be dominant symptoms. As far as is known psychodynamically, tremor is a concomitant of anxiety, increased muscular tension is an unconscious attempt to cope with problems, severe rigidity of the muscles (similar to extrapyramidal rigidity), as observed in battle reactions, is a defense against terror. (Grinker and Spiegel, 1945.) Waxy-flexibility is an expression of indifference to reality and of obedience. Extreme weakness is the expression of "giving up" as an attempt to solve unbearable conflicts. When these conditions are psychogenic, the treatment is psychotherapy.

Experimental Investigations. Muscular tension, waxy-flexibility can be induced and made to disappear in hypnosis.

In another experimental set-up, the subject is asked to hold a rubber bulb in each of his hands, but respond to signals only with his right hand. If the subject is confronted with conflict situations or is put under stress, tremors, or the pressure of the left hand can be recorded graphically even when responses of the right are successfully inhibited. (Luria, 1929.)

Tics

Tics are recurrent spasmodic movements of an extremity, of the head, the respiratory muscles, or the muscles of the eyelids, often closely resembling purposeful movements. They are at times due to lesions in the striate bodies of the brain, other times they are mainly psychogenic. In the latter case, they represent either defensive movement against unconscious dangers or are the expression of hostile and sexual impulses (e.g., a respiratory tic may contain a slurred obscene word).

Experimental Investigations. Chicks raised in incubators (on wire mesh) where there is no opportunity to peck from the ground—thus have an unsatisfied need for pecking—often exhibit a tic that resembles pecking. (Levy, 1938.)

STAMMERING

Stammering is a speech disorder characterized by a spasmodic repetition or blocking on some sounds, usually consonants, when these start words. Anybody may exhibit a slight transient stammer during stress. The severity of disorder in real stammerers also varies with stress situations, both passingly and over long periods of time.

The importance of stress is most dramatically illustrated in children who develop stammering, e.g., after a tonsillectomy, particularly at a time they are preoccupied with the newly discovered difference between the sexes. A sympathetic discussion, information, and reassurance may permanently eliminate the disorder.

Dynamically speech may imply self-assertion, hostile attack, and exposure. Low self-esteem, guilt, fear of punishment in the form of injury results in a spastic attempt to stop articulation. This further leads to over-compensatory haste to articulate and in this manner to an intensification of the spasm.

An important factor in stammering may be

uncertainty of cerebral dominance. (Orton, 1937.) Seventy-five per cent of the population is born with a tendency toward right-handedness which means that the speech center is in the left hemisphere and it is assumed then that impulses from the left hemisphere dominate the right. The other 25 per cent of the population is born either with a tendency to left-handedness or without any definite predilection ("ambidextrous"). In the latter group there may remain an uncertainty of cerebral dominance. If the left-handed child is trained to be right-handed, the same may occur—together with the arousal of many additional conflicts. In uncertain cerebral dominance the speech difficulty may be associated with reading difficulty, particularly "reversals," i.e., reading "saw" for "was."

Electroencephalography has been used to shed light on this problem. In normal individuals the α waves obtained from the two hemispheres are usually smooth and synchronous. In the stammerers, they are frequently out of phase with each other and often obliterated, especially when blocking occurs in speech. (Lindsley, 1940.)

The most generally effective treatment is speech training in a group, comprising frequent sessions. Such a procedure has many psychotherapeutic implications. The feeling of uniqueness, isolation, and inadequacy is lessened. Feelings of belongingness and companionship develop through new friendships. There is mutual encouragement through success. A general survey of the patient's situation and problems should always be made. Psychoanalysis is successful at times.

REACTIONS IN WHICH HEADACHE PREDOMINATES

Complaints of headache are common in personality disturbances.

Migraine. Migraine consists of periodic severe headaches, usually on one side, frequently accompanied by nausea, vomiting, constipation, or diarrhea. In more severe cases, the patient may have spots before the eyes, hemionopsia (not seeing objects on one side with either eye), paresthesia (sensation of pins and needles), hypoesthesia (diminished sensitivity), and weakness on one side of the body. The attack may last from a few hours to several days.

Migraine usually occurs as a reaction to situations of stress. As a rule, patients suffering

from these attacks are unusually ambitious and preoccupied with achievement and success. They are often perfectionists, to whom efficiency means a great deal; they are orderly to an extreme. A disturbance of the sexual function is common, manifesting itself in frigidity and disgust. (Knopf, 1935; Wolff, 1937.) Severe conflict over masturbation in late adolescence is not uncommon. There is also conflict over hostile reactions towards persons who interfere with the subject's perfectionistic strivings. The condition often occurs in several members of the same family.

The medicinal treatment, if it is a relatively mild headache, is coal tar products (like "aspirin"). Severe attacks can be stopped by the injection of ergotamine tartrate.

Experimental Investigations. A variety of experiments show that the headache in migraine results from distention of the cranial arteries. (Wolff, 1940.) Photographs made both before and during the action of ergotamine tartrate show that this agent reduces the amplitude of pulsations of the cranial arteries by about 50 per cent and thereby diminishes the intensity of, or terminates the headache. It has not been possible thus far to precipitate migraine attack through discussion of life situation.

REACTIONS IN WHICH DISTURBANCES OF THE CIRCULATORY SYSTEM PREDOMINATE

Peripheral Circulation; Raynaud's Syndrome. This syndrome is characterized by attacks, in one or more of the fingers, of pain, cyanosis (deep blue discoloration), or blanching, precipitated either through exposure to cold or emotional stress. If the condition is severe enough, small ulcers develop on the skin of the finger, the nail gets brittle, and, in very severe forms of the disease, part of the finger may be lost because of gangrene. The common focal conflict is guilt and fear of injury and abandonment, over-aggressive and sexual strivings, particularly as expressed through the use of the hands. The patient is either shy, self-effacing, and anxious, or self-controlled, idealistic, and persistent. The physical predisposition is obscure. This condition, and cold extremities in general, occurs more frequently in women either because the special type of conflict is more keen or because of metabolic differences. Psychotherapy has not been tried on an intensive enough scale to know how permanently effec-

tive it is. The physical treatment consists of protection of the hand against cold and, in severer cases, operative removal of sympathetic nerve supply to the extremity involved.

Experimental Investigations. The occurrence of vasoconstriction in the extremities during emotional stress has been studied by (1) the use of the plethysmograph, (2) measurement of the finger temperature, (3) colorimeter, and (4) capillary microscope. The use of the plethysmograph has been described in the general section of this article.

Capillary Microscope. The blood flow in the capillary bed under the nails can be observed directly with the microscope. In some accidental observations, it has been seen that the flow of blood in patients suffering from Raynaud's syndrome suddenly stopped when a new individual entered the room who upset the patient. (Fremont-Smith, 1939.)

Colorimeter. The color of the fingers varies from pink to blue, depending on the blood flow in the skin. The color change can be measured accurately with the colorimeter. It can be observed that during induced stress the color changes to bluish.

Finger Temperature. The most sensitive instrument is the radiometer which measures the amount of heat radiation from the part of the extremities studied. (Hardy, 1939.) This instrument was used in a detailed investigation of finger temperature changes in individuals without significant psychopathology and those with psychoneuroses and on two patients with Raynaud's syndrome. The stress situation was mainly the discussion with the subject of emotionally charged life situations either current or past. The discussion was often sustained for an hour. In 203 observations on 47 subjects, in experiments conducted with this method, there was a fall in finger temperature during emotional stress in all but three instances. In two subjects a slight rise in finger temperature occurred. The relative magnitude of the fall in finger temperature varied with the subjects even under comparable emotional stress as gauged by subjective statement, restlessness, facial expression, voice, topic of conversation. In some subjects the finger temperature regularly can be made to fall ca. twelve degrees centigrade, in others only two or four degrees. To some extent the readiness for the finger temperature to drop during emotional stress

was correlated with the individual's sensitivity to heat loss. If the individual needed more clothing in the same environmental temperature than other individuals, then the fall in finger temperature was apt to be great during emotional stress even if the clothing was otherwise adequate to enable the individual to maintain high finger temperature in a relaxed state for several hours. In the experiments on a patient suffering from Raynaud's syndrome, attacks could be precipitated (1) if the subject's clothing was inadequate so that the temperature of the fingers fell to a certain level; (2) in a cool environment even with adequate clothing if the life situation stresses were discussed with the subject for a half hour. The severest attacks were precipitated if inadequate clothing in a cool environment was combined with the discussion of life stresses. After sympathectomy, the fall in finger temperature during emotional stress disappeared and no attack occurred.

Résumé. There is experimental evidence to show that vaso-constriction commonly occurs in the extremities during emotional stress. The degree of vasoconstriction during comparable emotional stress varies from individual to individual. The environmental temperature and the effects of emotional stress combine in producing the degree of vasoconstriction. In Raynaud's syndrome, attacks can be precipitated in a cool environment by inducing emotional stress. The impulse to the blood vessels is mediated through the sympathetic nervous system.

ARTERIAL HYPERTENSION

Arterial hypertension is characterized by increase in the blood pressure without, in the early stages, structural damage being demonstrable in the blood vessels. The normal limits of the blood pressure are debatable, but a consistently elevated systolic pressure over 150 and consistently elevated diastolic over 70 is definite elevation.

Of 93 patients with hypertension 86 showed significant emotional factors in the production of symptoms. (Weiss, 1942.) The focal conflict in hypertension commonly revolves around constellations of hostility and dependency. (Hill, 1935; Menninger, 1938; Saul and Alexander, 1939; Binger, Ackerman, and Cohen, 1945.) This aggression may come from a variety of sources, such as frustrated dependency needs, hurt self-esteem, threat to a dominating posi-

tion, rebellion against authority, and sexual injury. The personality is apt to be one of two types:

(a) An active individual who aggressively participates in group activities. In this type, hostility is connected with hurt self-esteem and threat to position and achievement. The aggression may be overt and excessive.

(b) An outwardly calm and obliging individual, not without initiative but obedient to rules.

The somatic predisposition to hypertension is obscure. In some cases a constitutional tendency is likely: in some families several members in several generations suffer from this disease and die finally of cerebral hemorrhage or heart attack. This illustrates also that hypertension, if it continues long enough, is apt to lead ultimately to structural changes in the vascular system. Psychotherapy, particularly psychoanalysis, can be very effective in bringing the blood pressure to a lower level when the patient's conflicts are resolved. (Hill, 1935; Mittelmann, 1945.) In severe cases, an operation can be performed which consists of severing the sympathetic nerve supply to the blood vessels. (Thoracolumbar Sympathectomy.)

Experimental Investigations. Blood pressure is measured in human beings by the sphygmomanometer. A cuff, connected with a manometer recording the pressure, is put around the arm and is inflated with air to a point where the rhythmic sounds over the artery disappear because of the cessation of the blood flow. Sound is present only when the artery is partly compressed. As the air is gradually let out of the cuff, the appearance of the first sound over the artery signals the reestablishment of the circulation, that is the systolic pressure (systolic indicating contraction of the heart, maximum pressure). As the pressure is gradually lowered, the sound disappears, indicating the diastolic pressure.

Fleeting rise in blood pressure was observed in response to startle and lying. (Marston, 1917.) Sustained rise in the blood pressure occurred in 13 students examined before and after an important six-hour examination. It was very high, 165 mm. on the average, beforehand, 152 mm., still high, afterwards. In some students it was high for several days. (Tigerstadt, 1926.) Some "normal" subjects as well as patients with cardiovascular disorders may

show normal pressure, during periods of life stress, if they are at rest; but the rise in pressure is found to be excessive during such periods in response to a standard physical exercise. (Wolf and Wolff, 1946.) The rise in pressure is caused mainly by vasoconstriction. By a preliminary operation a bit of the lining of a dog's intestine was grafted into the skin while still retaining its own proper nerves and blood vessels. Thus a sample of the intestinal mucous membrane was exposed to view. Whenever this dog was frightened, as by the approach of a strange person, the membrane blanched. (Barcroft, Florey, and Drury, 1929.)

The significance of anxiety is further illustrated by accidental observation on kidney function on two subjects who got into acute states of anxiety while the circulation of the kidneys was being measured. The renal blood flow was decreased by about 40 per cent and there was an increase in blood pressure. It may be mentioned that a diminished blood flow in the kidneys liberates a substance which raises the level of the blood pressure. (Smith, Goldring and Chasis, 1938.) In a patient who was under psychoanalytic treatment for hypertension, the blood pressure was measured regularly before and after the analytic interview. Whenever the patient's emotional tension, particularly hostility and anxiety, was reduced as a result of the analytic interview, the systolic blood pressure averaged 10-20 points lower after the interview. (Alexander, 1939.)

Résumé. Experimental evidence shows that blood pressure can rise in fear and resentment, and the circulation in the kidneys may be abruptly diminished in fear. In patients suffering from hypertension, the blood pressure may be lowered when the conflict situation is resolved.

DISORDERS OF THE HEART FUNCTION

The heart action may show a variety of disorders in connection with personality problems: rapid or irregular heart rate, pain in the heart region. These disorders commonly represent one symptom of a psychoneurotic reaction pattern. One of these, namely neurocirculatory asthenia, is a fairly well defined syndrome.

Neurocirculatory Asthenia. The syndrome is characterized by rapid and labile action of the heart (over eighty beats per minute), difficulty

in breathing, often with feelings of faintness and dizziness, and cold extremities. The syndrome has also been called disordered action of the heart, soldier's heart, and effort syndrome. The syndrome was first observed during the American Civil War in soldiers (Da Costa, 1871), then during the First World War. (Lewis, 1918.) The condition is essentially an anxiety state, particularly aggravated by exercise. The patient is afraid of physical effort, constantly anticipates it, and, in this sense, is constantly engaged in it. The syndrome offers a particularly striking example of the combined effect of anxiety and of physical effort. Physical effort comes to represent aggressive and sexual behavior with the attendant anxiety, and in soldiers, of course, there is unconscious rebellion against discipline and fear of injury and loss of life.

In experimental investigations, it can actually be observed that the patient's pulse rate rises very rapidly during moderate effort. The respiratory tracing, even at rest, shows irregularity of level and of depth of breathing. (Christie, 1935.) Patients with such a condition are not capable of sustained physical effort. Treatment is psychotherapy.

Coronary Disease of the Heart. The coronary artery is the blood vessel that supplies the heart muscle with blood. Either a spasm or partial occlusion of the coronary artery or its branches leads to severe attacks of pain in the heart region.

The personality of individuals with coronary disease is apt to be perfectionistic, driving, with a steady devotion to goals. Impulsive changes in life situations are infrequent. The conflict constellation connected with coronary disease itself is apt to be either resentment over failure, and thus over not living up to ideals, and over humiliation; or that of resentment over rejection with fear of abandonment and guilt over hostile and sexual strivings.

Coronary disease of the heart is not infrequently found in families that are predisposed to vascular diseases. Physical treatment consists of prolonged bedrest with oxygen administration and injection of morphine to relieve pain after an occlusion, and administration of vasodilators (e.g., amylnitrite) to relieve the spasm. Psychotherapy can be very effective in diminishing the frequency and severity of attacks,

and the patient may be able to engage in a moderate amount of physical effort when previously even a small effort brought about pain.

Congestive Heart Failure. Heart failure may result from coronary disease, from hypertension, or from rheumatic heart disease. The failure results from the excess load placed on the heart or through direct weakening of the muscle. Emotional stress may intensify the failure by directly affecting the blood pressure and the coronary artery or through nervous and humoral influence on the heart function. The physical treatment of heart failure is rest in bed and the administration of digitalis and diuretics. At times recovery is much helped by psychotherapy.

Experimental Investigations. It has been mentioned that the heart rate usually increases during fear, anger, lying, and sexual excitement, particularly orgasm. The cardiograph gives a continuous record of the heart rate. The electrocardiograph is led through electrodes and flexible leads—which can be as long as 100 feet, permitting the subject to work or play freely while his heart rate is being recorded—to a graphic registering device. During sexual behavior of a married couple, the heart rate rose, over some seconds, to 146 beats per minute in orgasm. (Boas and Goldschmidt, 1932.)

The electrocardiogram is a record of the electric waves produced by the heart muscle in the course of its contraction and relaxation. It has been found that the electrocardiogram may show pathological changes during intense emotional reactions (anxiety, tension, resentment, and sexual excitement), and these pathological changes disappear when the emotional disturbance is relieved. In a study of 41 patients who suffered from personality disorders with intense emotional reactions, two showed such abnormal findings. (Loftus, Gold, and Diethelm, 1945.)

Résumé. There is experimental evidence to demonstrate that the heart rate may increase during anger, fear, anxiety, and sexual excitement. Pathological changes in the electrocardiogram may occur correlated with intense fear, anger, and sexual excitement. In patients with heart failure and with coronary disease, symptoms may diminish considerably when the conflicts are resolved.

REACTIONS IN WHICH DISORDERS OF THE RESPIRATORY SYSTEM PREDOMINATE

Vasomotor Rhinitis,¹ Common Cold, Sinus Disease. Vasomotor rhinitis consists of congestion of the nasal mucous membrane and of the conjunctivae of the eyes and a thin, watery secretion from the nose together with sneezing and with itching of the eyes. The personality types may vary. The common stress situation is that of frustrated dependency longing, directed particularly towards the mother or mother substitute. There may also be strong sexual curiosity relating to the function of reproduction and desire to look and smell. The result of the conflict may be congestion of the nasal mucous membrane with damage of both olfactory and visual perception. (Wilson, 1941; Saul, 1941.)

At times frequent colds and sinusitis develop on a similar emotional background because the circulatory disturbance leads to lowered resistance to infection.

Experimental Investigations. Daily observations of nasal functions and structures, including changes in circulation, swelling, secretion, evidences of obstruction, and pain, were made on groups of healthy and sick persons. Daily records were made of the subject's life situation, attitudes, dominant emotional reactions, fantasies, and dreams. It was found that abject fear and dejection and disgust were associated with pallor of the nasal mucosa and decreased secretion; on the other hand, anxiety and

¹ The asthmatic syndrome, urticaria, and vasomotor rhinitis are not always or completely emotionally determined, although there often are strong emotional factors in the total picture. Frequently the condition is caused mainly or entirely by the individual sensitiveness to an external protein in the form of food or something which the patient inhales (allergen). The offending agents may be horsehair or some other animal hair, pollens, beef, pork, etc. The attack occurs whenever the patient is exposed to the offending agent, and it disappears if this substance is eliminated. In some instances the patient is sensitive to an agent, but attacks occur only during periods of emotional stress. In the allergic physiochemical reaction, a histamine-like substance is liberated in the body. This substance stimulates certain nerve endings, or the capillaries are affected directly, and the various symptoms are produced. This histamine-like substance is produced even in conditions in which the psychogenic factor eventually is the most important determinant. Allergic reactions often show familial incidence.

resentment were associated with redness and swelling of the mucosa, increased secretion, and obstruction. Weeping, as well as the feeling of being on the verge of tears, were associated with pallor, extreme swelling of the nasal mucosa, profuse secretion, and obstruction with complaints of difficulty in breathing. (Goodell and Wolff, 1946.)

BRONCHIAL ASTHMA

Bronchial asthma is characterized by attacks of difficulty in breathing, wheezing sounds over the chest, and increase in eosinophilic cells in the blood. The attacks are caused by an involuntary contraction of the bronchial muscles. This spasm interferes with the respiration during both inspiration and expiration, but particularly during expiration. This contraction of the bronchial muscles is mediated chiefly through the vagus nerve.

The asthmatic attack is correlated mainly with attitudes of anger and hostility, particularly towards a dependency figure (mother or her substitute) and the resultant fear of abandonment. (French, 1939.) In 37 of 50 unselected asthma patients emotional factors were significant in the maintenance of the illness. (McDermott and Cobb, 1939.) The multiple psychogenic factors are: (1) physical illness in childhood (either onset of asthma for allergic reasons in childhood or whooping cough or bronchitis) during a period of emotional conflict, e.g., attachment and hostility towards the parents; (2) parental attitude towards the child during this period, concentrated on the child's illness (the mother particularly); (3) current conflict in adulthood (e.g., wife separated from her husband). (Deutsch, 1939.)

The common personality type in asthma is either the smiling, unruffled, or the openly dependent, emotionally unstable individual. Their fantasy life is apt to be very lively with a fantasy occasionally carried into action. (Dunbar, 1943.)

In the asthmatic attack, the administration of adrenalin, ephedrin, or atropin is as a rule immediately effective, because the bronchial muscles are relaxed. The first two of these drugs accomplish this by stimulating the sympathetic and the atropin does this by paralyzing the vagus nerve. If the substance to which the patient is allergic can be determined either by skin tests or by elimination diet, then the elim-

ination of the substance may stop the asthma. Psychotherapy is often very effective even in patients who have suffered from asthma for twenty years.

Experimental Investigations. The respiratory curve and the amount of oxygen consumption (basal metabolic rate) of several patients was determined, first in a period of relaxation, then while they thought of disturbing events. During disturbed periods, respiration became more frequent and deeper, the inspiration-expiration angle grew sharper, and the oxygen consumption rose considerably. (Finesinger, 1939.)

Respiration can be recorded by three methods: (1) recording the changes of the chest girth with the respiratory movements by means of an elastic belt strapped around the chest; (2) breath current recorder, by means of a gas mask with valves—during expiration the connected tambour rises, during inspiration it falls; (3) body plethysmograph: The subject is seated inside an airtight box. The connected tambour rises during inspiration and falls during expiration. In experiments with uniform methods and stimuli, it has been found that the breathing in excitement is both fast and deep. The ratio between the duration of inspiration and expiration (Storing, 1905), in ordinary quiet breathing, averages about 0.4 to 0.45, somewhat less than half. This ratio tends to be high in excitement. It increases after lying. (Benussi, 1914.)

There is suggestive evidence that the shape of the respiratory curve at rest is correlated with some personality tendencies. Inspiratory spikes, rounded tips at inspiration, and breath-holding at inspiration seem connected with psychological intaking tendencies; shallow respiration, rounding of expiratory tips, and breath-holding at expiration, with psychological eliminating tendencies. (Alexander and Saul, 1940.)

Résumé. Experimental investigations demonstrate that the rate and curve of respiration may be altered during emotional stress. Asthmatic attacks may lessen in severity and frequency or may disappear entirely when the patient's conflicts are resolved.

PULMONARY TUBERCULOSIS

The tubercle bacillus may cause chronic inflammation in any organ of the body. The most common site is represented by the lungs. Reac-

tions to life situations may act as factors lowering the resistance of the individual to this infection. (Jelliffe and Evans, 1919.) Reactivation of the inflammatory process just at the time of the planned discharge from the sanatorium is not an uncommon observation. The fear and reluctance to leave a sheltered environment may be a factor in it. At times the onset and recurrence of the illness seems correlated with a largely unconscious defiant, self-destructive refusal of the patient to commit himself to a course required by an actual and internalized authority (usually father figure).

Psychotherapy may be a useful adjunct in the treatment, which is mainly adequate food, rest, and general hygiene.

REACTIONS IN WHICH DISORDERS OF THE SKIN PREDOMINATE

The skin disorders that are connected with personality problems are excessive perspiration of the armpit and of the extremities with thickening and sensitiveness of the soles of the feet (Kuper, Fisher, 1945) warts, itching, and prurigo. This latter condition is characterized by localized itching and small nodules forming as a rule on the outer surface of the arm or on the neck. These disorders have been identified as psychosomatic either because they start or become worse during stress situations or because they improve or are cured by psychotherapy, at times of the hypnotic type.

ACNE

Acne is a disorder of the skin of the face and of the back consisting of the formation of pimples in an oily skin. It usually starts after puberty and very frequently disappears spontaneously. In other instances it persists. X-ray treatment is very effective in changing the texture of the skin so that the disorder disappears. Nevertheless this is in part a psychosomatic disorder. In some individuals, acne appears during stress situations and disappears when the stress is resolved and reappears again concomitantly with the emotional disturbances. Endocrine disturbance very likely forms its background. The psychological conflict centers mainly about the problem of sexual impulses and fear of exposure together with feelings of worthlessness and guilt because of rejection.

URTICARIA

Urticaria (hives) consists of itching and reddening of the skin and the formation of hives which form in one place, disappear, and appear in another place. It usually occurs in attacks, often due to ingestion of food stuffs to which the individual is sensitive. The most common emotional problem encountered in the patient is frustrated dependency longings. (Saul, 1941.) Together with that, there may be desire for exhibitionism or fantasy of returning to the womb. (Mittelman, 1941.) Psychotherapy can be effective. The elimination of the allergic substance from the diet of the subject can also be effective. Adrenalin is administered for immediate relief of the attack.

Experimental Investigations. The experimental investigations demonstrating the correlations between emotional reactions and changes in the skin have been mentioned in various parts of this section. They were (1) increase in palmar sweat secretion; (2) vasoconstriction in the extremities during emotional stress; (3) the production of blisters in hypnosis by the suggestion of touching the hot iron; and (4) the production of swelling of the hand and its disappearance in hypnosis.

Résumé. There is experimental evidence to show that vasoconstriction, vasodilation, swelling, and blister formation may occur in the skin during emotional stress. Excessive perspiration, thickening of the skin, itching, prurigo, acne, and urticaria may appear during periods of stressful life situations and may be benefited by psychotherapy.

REACTIONS IN WHICH GASTROINTESTINAL DISORDERS PREDOMINATE

Loss of appetite, attacks of nausea, "lump in the throat" are common minor symptoms in psychoneurotic reactions and can be distressing as anxiety concomitants or equivalents.

CARDIOSPASM

This condition consists of a spastic contraction of the circular musculature of the cardia (entrance to the stomach). As a result, food accumulates in the lower portion of the gullet which becomes dilated. The symptoms are pain and vomiting. The condition is correlated with anxiety states and hostile rejection of food as a token of affection with strong desire to accept

it. ("I cannot swallow this situation.") (Weiss, 1944.)

Experimental Investigation. While being observed with the oesophagoscope, the oesophagus of a patient relaxed when he was assured that he would get a job and his home situation would be straightened out. Total spasm of the oesophagus occurred when he was asked what he would do if he had to remain poor and unemployed. (Faulkner, 1940.)

PEPTIC ULCER

A peptic ulcer is a small wound which develops either in the stomach itself or in the duodenum, the portion of the bowels immediately below the stomach. The patient complains of recurrent pain in the upper abdomen usually when the stomach is empty; the taking of food usually relieves the discomfort.

The most common personality type seen in this disorder, is that of the ambitious, hard driving, emotionally controlled individual. (Draper and Tourain, 1932.) The conflict situation is resentment, anxiety, and guilt over frustrated strivings for achievement, self-esteem, and dependence. (Alexander, Bacon, and Levey, 1934.) The stomach complaints finally represent the results of wanting love through being fed, attacking through devouring, and a plea of helplessness through suffering. (Mittelman and Wolff, 1942.) The physiological predisposition is undetermined.

Physical therapy consists of dieting (milk, cream, eggs) which is usually promptly effective, and of the administration of medicines which bind the acidity of the stomach. Psychotherapy should always be given.

Experimental Investigations. In experiments with fleeting standardized stimuli, it was found that the tension and peristalsis of the stomach increases slightly in pleasant and affirmative emotional situations and diminishes slightly during unpleasant emotional experience. (Brunswick, 1924.)

In combined experimental and pathological investigations, anxiety, resentment, and pleasure producing experiences were suggested to subjects in hypnosis. It was found that acid secretion at times increased, at times decreased, during the same emotion in different subjects, but the reaction of each subject was constant for each emotion. (Witkower, 1935.)

Extensive investigations were conducted on

normal individuals, on individuals in anxiety states, with a burning in the stomach as the chief complaint, and on patients with peptic ulcer, using discussion of life experiences as stress stimuli. The gastric secretion was obtained through a nasal catheter, the stomach motility was registered by means of a swallowed, inflated balloon connected with a tambour. It was found that the secretion of hydrochloric acid and peristalsis of the stomach increased during mixed reactions of anxiety, anger, embarrassment, and guilt. In patients with peptic ulcer, pain appeared together with these phenomena. In one of the subjects, after a period of most intense anger, blood appeared in the contents of the stomach, indicating changes in the circulation also. (Mittelman and Wolff, 1942.)

In a subject who, as a result of an operation, had an opening of the stomach in the abdominal wall, extensive observations were made on the correlation between emotional reactions and gastric function. During panic reactions there was a temporary paling of the mucous membrane of the stomach and diminution of secretion and peristalsis. During anger and anxiety, there was an increase in the same functions and a blanching and swelling of the mucous membrane. In such a state, the mucous membrane was easily injured. If the mucous was kept away from a wound in the stomach wall, the wound did not heal but developed into an ulcer. (Wolf and Wolff, 1943.)

Résumé. There is experimental evidence that gastric motility, secretion, and circulation may increase during anxiety, anger, embarrassment, and guilt. In this condition, the mucous membrane of the stomach may be easily vulnerable and an ulcer may form. Complaints of peptic ulcer often arise during periods of emotional stress. Psychotherapy may be a useful adjunct in treatment.

DIARRHEA, MUCOUS COLITIS, ULCERATIVE COLITIS, AND CHRONIC CONSTIPATION

Mucous colitis is characterized by frequent bowel movements or constipation accompanied by pain and discharge of mucous and at times blood. (In ulcerative colitis, ulcers are also present.) Mucous colitis correlated with resentment, anxiety, and guilt in 53 out of 57 cases studied and is to be considered a psychosomatic condition. (White, Cobb, and Jones, 1939.) So

is ulcerative colitis if there is no serious primary infection present. A common stress situation in the latter is that of frustrated dependency with hostility and suicidal trends. (Daniell, 1940.) The emotional formula in diarrhea may be "I am giving of myself to the world; I deserve to be looked after." Ulcerative colitis is a very serious illness and may end in death. The treatment is dietary and medicinal. Psychotherapy may be effective.

Chronic constipation is characterized by infrequency and hard consistency of spontaneous bowel movements. The psychological formula is the opposite of that of diarrhea: "I am not receiving love and care, therefore I will give nothing to the world." (Wilson, 1934; Levine, 1934.) Constipation at times arises passingly during periods of stress, at other times it is a chronic condition, and at times it alternates with diarrhea.

HEMORRHOIDS AND FISSURES

Hemorrhoids and fissures of the anus may arise as complications of both diarrhea and constipation. The condition can further be aggravated by a tight sphincter muscle, which spastic state is correlated with the emotional tension.

The experimental evidence indicates that the colon may become spastic (contracted) or atonic (too relaxed) in periods of emotional stress.

OBESITY AND ANOREXIA NERVOSA

Cultural patterns as regards the desirability of stoutness or leanness vary with cultural groups and with the period of time. This applies particularly to women.

OBESITY

Excessive eating is a method of relieving emotional tension by using pleasure in food and devouring as consolation and by substituting food for affection (Bruch, 1940) and for sexual gratification. Overweight may result secondarily in moderate rise in blood pressure, in irregular menstrual periods, and in a slight lowering of basal metabolism. If the patient can diet successfully, these effects disappear.

ANOREXIA NERVOSA

As a rule observed in women, anorexia nervosa (Gull, 1884) is characterized by vomiting, loss of appetite, considerable loss of

weight, low basal metabolism, and the stoppage of menstruation. The condition if untreated can be fatal. The patients are usually uncooperative, irritable, and hostile (Rahman, Richardson, and Ripley, 1939). Often for many years the patients were overeating and were stout, then started to diet in order to reduce, and finally developed anorexia nervosa. The usual conflict situation is resentment towards the mother because of feelings of rejection and rivalry together with fantasies of oral impregnation. At first the emotional tension is resolved by overeating, food being substituted for affection. However, the resultant obesity represents humiliation, exposure, and anticipated rejection by men. The dieting at first is an attempted remedy of these secondary consequences but finally ends up in the rejection of food as a symbol of affection and of sexuality. (Waller, Kaufman, and Deutsch, 1940.) Glandular predisposition, either in the direction of obesity or anorexia nervosa, is a controversial question. With symptoms developed there may be an excess of the gonadotropic (anterior pituitary) hormone (McCullough and Tuffer, 1940) and either an excess or a deficiency of estrogenic hormone. (Moulton, 1942.) Psychotherapy is difficult but can be successful.

REACTIONS WITH DISTURBANCES IN SUGAR METABOLISM

Diabetes (Hyperglycemia). Diabetes consists of continuous elevation of the sugar above 120 mg. in 100 cc. of blood, which usually spills over into the urine and at times leads to acidosis and, if untreated, to coma. The condition is due to an insufficiency of the hormone of the pancreas which controls sugar metabolism. It is a common observation that during periods of anxiety the amount of sugar in the blood and urine increases in spite of a standardized diet. Depression is a common symptom. (Menninger, 1935.) The conflict situation in individuals studied in detail is that of fear of being overpowered and injured because of hostile, rebellious and sexual strivings. (Daniels, 1936.)

HYPOGLYCEMIA

If the blood sugar falls below a certain level (sixty to forty mg. per 100 cc. of blood) confusion, dream states, and manic excitement may appear. Marked lowering of the blood

sugar is usually due to an over-functioning of the pancreas caused by a benign tumor (adenoma). However, a less dramatic fall in blood sugar level may be correlated with personality problems and emotional reactions. It may occur during conditions characterized essentially by motor tension but at times also by depression. Attacks of extreme weakness, tremulousness, sweating, and vertigo may occur (Rennie and Howard, 1942). It may also be correlated with a syndrome characterized by consistent and prolonged feeling of fatigue. This latter syndrome has been called hypoglycemic fatigue (Szondi and Lax, 1929; Alexander and Portis, 1944.) The outstanding features are apathy, aimlessness, and a repulsion against the routine of everyday life. The fatigue is chronic or it appears in acute attacks.

The psychological picture represents a reaction of disappointment and defiant self-incapacitating refusal to be active: "I cannot have what I want; I will not play any more."

Experimental Investigations. Cannon's observation (1915) of the appearance of sugar in the urine during fear and rage has been mentioned. For the demonstration of hyperglycemic, as well as of hypoglycemic reactions, the so-called sugar tolerance test is a more sensitive procedure than a single determination of the blood sugar under basic conditions. Either 50 or 100 grams of dextrose are administered by mouth or one-third gram of dextrose is injected into the blood per kilogram of body weight. Blood samples are withdrawn a half hour, one hour, 1½ hours, two hours, and sometimes three hours after the administration. In the normal individual, there is a moderate rise in blood sugar for about one hour, with return to the previous level after two hours. In psychoneurotic and psychotic patients, anxiety, tension, fear (particularly panic reactions), as well as resentment, hate, and anger, may be accompanied by an increased level of the blood sugar during fasting; together with that, or often even when the fasting level is normal, the curve for dextrose tolerance may be elevated. (Diethelm, 1936.) In the hypoglycemic states described above, the dextrose tolerance curve shows a lack of rise in blood sugar or an actual fall during periods of psychiatric symptoms. If psychiatric management relieved the condition, the "flat" tolerance curves disappeared. (Rennie and Howard, 1942.) The injection of atropine,

assumedly through inhibiting the vagus nerve which stimulates secretion of insulin, relieves both the hypoglycemia as well as the fatigue. (Alexander and Portis, 1944.)

Treatment. The physical treatment of diabetes consists of dieting and the administration of insulin. Psychotherapy may diminish the amount of insulin needed. Psychosomatic phenomena of hypoglycemic reactions may be relieved by psychiatric management. However, the administration of atropine may cut short the vicious circle of fatigue, the resultant disappointment in oneself, and guilt. Relief of the patient's symptoms may increase his hopes and make him more amenable to psychotherapy.

Résumé. There is experimental evidence to indicate that the blood sugar level may be elevated under basal conditions or during dextrose tolerance test in states of fear and anger; and may be lowered during states of tension with depression and fatigue. Psychotherapy may be beneficial in diabetes as well as in hypoglycemia.

REACTIONS IN WHICH DISTURBANCES OF THE URINARY BLADDER PREDOMINATE

Enuresis, Difficulty in Voiding, and Frequency of Urination. Enuresis, not uncommon in children, consists of involuntary voiding, as a rule in sleep; hence it is commonly called bed-wetting. The mechanism of voiding consists of a simultaneous contraction of the longitudinal muscle of the bladder, relaxation of the sphincter (circular) muscle of the bladder and urethra, and, during part of the time, contraction of the abdominal muscles. At times the opposite process is observable in adults, namely difficulty in starting the stream because of inability to relax the sphincter muscle. Frequency of urination, when it is not connected with increased urinary secretion, consists of the urge to urinate even when there is relatively little urine in the bladder. All three symptoms may occur concomitantly with anxiety reactions. Enuresis and frequency often are connected in addition with psychological equating of sexual and urinary function or, in children in response to the birth of a new sibling, they are sadistic substitutes for self-assertive aggression. (Despert, 1944.) Difficulty in starting the stream in addition is connected with embarrassment and shame and the feeling of exposure. This occurs mainly in public toilets. If frequency of urination is severe and persists over many

years, the bladder may finally shrink. This, however, happens very rarely.

Treatment Is Psychotherapy. Improvement of bladder control in children by conditioning has been achieved on a limited scale. There is an electric circuit that gets closed by moisture and a bell rings. After such repeated occurrences, the child wakes spontaneously in response to the urinary urge.

Experimental Investigations. Excitable monkeys, when frustrated, in addition to increased motor behavior, also defecate and urinate.

It is extremely rare that a normal dog urinates in the experimental room or on the stand, even though he may be kept there for seven hours or more. Dogs with experimental neurosis may urinate as many as thirty times an hour—anywhere in the experimental environment, not infrequently on the food. (Gantt, 1942.)

REACTIONS IN WHICH SEXUAL DISTURBANCES PREDOMINATE

The psychosomatic problems connected with sexual activity can be divided into sexual disturbances correlated mainly with changes in life situation and those correlated with primary hormonal changes.

HORMONAL UNDER-FUNCTIONING

In either sex, diminished supply of hormones may come (1) from inadequate development, (2) from operative removal of the gonads, (3) from decline in function because of age. In all of these conditions there are both similarities and differences between the male and the female sex. Inadequate or delayed development is apt to be more disturbing in the male. Operative removal may be equally disturbing in both but more so in the male. Decline in functions because of aging is likely to be more disturbing in the female.

Disturbed Development. Adiposogenital Dys trophy: Inadequate sexual development is usually due to inadequate functioning of the anterior lobe of the pituitary gland. At times it is associated with inadequate growth and underweight. A more common syndrome is characterized by overweight, low basal metabolism, and at times undescended testes. In either condition, the psychological picture may be the result of lack of drive together with a retreat into a passive, submissive role, seeking maternal protection and preferring to play with girls. The

condition is associated with feelings of inadequacy and the feeling of having been injured (castrated). At other times, a reaction develops against these attitudes and a hostile, attacking, defiant behavior results. (Mittelman, 1938.) Physical treatment consists of thyroid substance by mouth and the injection of anterior pituitary sex stimulating, and particularly of male sex hormone (androgen). In the majority of cases, this treatment leads to adequate development. Psychotherapy is needed at times to eliminate the after-effects of the condition. (Mittelman, 1938.)

Surgical Removal of the Gonads. This usually results in the male in feelings of inadequacy, diminished interest and drive. There are, however, cases on record which show that even such a reaction has a large psychological component, because under favorable circumstances, some patients are able to continue, or recover adequate sexual activity if the removal took place after reaching adulthood and engaging in full sexual activity. With this, the lack of drive disappears. The injection of androgen (testosterone) restores adequate sexual activity. In the woman, the removal of the ovaries has the same effect as the decline in function because of age.

Menopause. The condition is characterized by cessation of menstruation and not infrequently by the appearance of hot flushes with excessive perspiration, dizziness, headaches, irritability, and depression. The hot flushes and the excessive perspiration are very likely due not to diminished estrogenic sex hormone but to excess of anterior pituitary hormone. Sexual receptivity and orgasmic ability are retained in the healthy woman after menopause. The psychological symptoms are the result of a combination of direct effects of the endocrine imbalance and of the individual's reaction to these changes. The endocrine changes represent a double threat: (1) distressing, uncontrollable bodily symptoms, and (2) aging and the final loss of fulfillment of life-long longings. The administration of ovarian follicular hormone is largely effective in removing the physical symptoms. Additional psychotherapy eliminates psychological symptoms also. In severe depression, electroshock treatment is effective in a considerable proportion of the cases (see later).

In the majority of cases, decline of sexual function in the male is very gradual and causes

no serious disturbance, although in some instances depression occurs. The decline in function can be remedied by the injection of testosterone.

Psychogenic Underfunctioning—Frigidity and Impotence. In the overwhelming majority of cases, impotence in the male and frigidity in the female are psychogenically determined. The most common form of impotence or disturbed potency in the male is inadequacy and short duration of erection with a premature occurrence of ejaculation. Rarely, the disturbance manifests itself in inability to reach an ejaculation. In the female, frigidity as a rule means either inability to reach an orgasm through vaginal stimulation or even through clitoral stimulation or, in milder instances, there is difficulty in reaching an orgasm in either way. In severe instances, there is in addition disgust experienced towards the sexual act. At times, orgasm is experienced by, or is more enjoyed by masturbation or by homosexual contact. The average time required by healthy individuals to reach sexual climax is two to 15 minutes. The physiological changes occurring during orgasm are not well known, particularly in the woman. There is increase in pulse rate, increased perspiration, deep breathing, general muscular contraction followed by general relaxation and not infrequently sleep. Even in the presence of these reactions, there may be inadequate subjective enjoyment and inability to relax and feel satisfied after the occurrence. Disturbances in potency are correlated with total personality problems of very complex nature. The dominant aspect is fear and reluctance to reach out towards the other individual, hostility and fear of counter-attack, particularly in the form of genital injury. The treatment is psychotherapy.

Premature and Over-function. The only primary pathological glandular sexual over-function is the one observed in premature sexual development as a result of tumors of the gonads or of the cortex of the adrenal gland. In such rare instances, the children show all secondary sexual characters and the premature development of the penis, the girls menstruate, and both sexes may show active increased desire for sexual behavior. The treatment of the condition is operation.

Some manifestation of sexual activity and

sexual interest is normal before puberty. Excessive masturbation, e.g., daily or several times a day in children or after puberty, is a psychogenic disturbance. So is promiscuity and continuous drive for sexual relations. The emotional background for these disturbances is a total personality disturbance in which three aspects may predominate: (1) using the sexual activity as a means of attaining other emotional goals such as self-magnification or love; (2) a compensatory overactivity against fear of genital injury; and (3) a defiant reassertion of the pursuit of a forbidden goal. Treatment is psychotherapy of the individual and of his environment.

Perversions and Homosexuality. The definition of perversion is somewhat difficult because cultural customs and preference play a large role. In our cultural set-up, perversion could be roughly defined as alteration in the aim of sexual activity where the ultimate goal is not genital union with a heterosexual object. Perversions are predominantly psychogenically determined, although the tendency for it may be facilitated by relative innate propensity for the use of one or another organ, the function of which is a source of pleasure (mouth, excretory organs). The difficulties represent disturbances of the total personality in which the following aspects may predominate: (1) substitution of one function for the other because it is considered unconsciously less dangerous; and (2) defiant assertion of a forbidden impulse.

Homosexuality. Homosexuality, in its fully developed form, consists of genital gratification by one of the individuals of the same sex. The physiological background, e.g., hormonal imbalance, either as a determinant or as increased tendency, is uncertain. In the majority of instances, there is no evidence either for a predominance of the hormones or of secondary sexual characters of the opposite sex. Psychogenically the disturbance represents a total personality disturbance in which the following aspects may predominate: (1) fear of the opposite sex in terms of injury and humiliation; (2) the fear of results in rejection of the opposite sex, but the desire for closeness makes the individual turn to members of his own sex who are also feared, but less so; (3) as a result of developmental problems, identification with a member of the opposite sex; (4) submission to

the feared member of the same sex by way of obtaining love, support, and forgiveness; and (5) defiant assertion of a forbidden impulse. The only present known treatment is psychotherapy, both for perversions in general and for homosexuality in particular. It is often a difficult task, because these disturbances have a very great value as sources of pleasure. However, it is often successful if the individual is deeply dissatisfied with his sexual activities and has a strong desire to change them.

Disturbances Connected with Menstruation. Menstruation is one phenomena in the cyclical changes of the female hormonal activity. The disturbances comprise either diminished or absent menstrual flow, excessive menstrual flow, or increased psychological distress in connection with menstrual flow. The cessation or excess of menstruation may be connected with primary disturbances in hormonal function. One of the most important of these, namely menopause, has already been discussed. Here three syndromes will be presented particularly:

Premenstrual or Menstrual Tension. Premenstrual tension is the more common of the two. It consists of moodiness, irritability, and in more severe reactions, anxiety states. As a rule the symptoms disappear when menstruation begins. In other instances, however, the symptoms continue or become intensified during menstruation.

If the symptoms are severe, they represent total personality reactions. The dominant features are (1) reaction to an unlocalized tension; and (2) rebellion against the feminine role and increase in anxieties centered around interhuman relations as symbolized by the feminine role. At times the hormonal level (see below) is excessively high or remains high when it ought to decline, in such patients. (Benedek and Rubenstein, 1939.) It is difficult to decide in such instances to what extent this characteristic of the hormonal level is psychologically determined.

Cessation of Menstruation. Temporary delay in menstrual period is not infrequently seen as occurring correlated with stress situations. Of rarer occurrence is "false pregnancy" (pseudocyesis) in which the woman does not menstruate for many months, together with presenting enlargement of the abdomen due to accumulation of gas. There is an excess of

gonadotropic (pituitary) and a diminution of estrogenic (follicular) hormone (with persistence of the corpus luteum) as in pregnancy. (Moulton, 1942.) The psychogenic background of the disturbance is a fantasy of being pregnant, that is, the desire for a child. However, desire for a child that is accompanied by such phenomena is a total personality reaction, and pregnancy represents a desperately desired fulfillment of the role as a woman or the idea of self-sufficiency, possessing everything within oneself, including the male organ ("narcissistic" desires), and the desire to be looked after. These factors may dominate the picture in temporary cessation of menstruation also. Another dominant element in that situation is a plea of helplessness, together with the need to be looked after as an expectant mother.

Dysmenorrhea (Painful Menstruation). The pain is cramplike in character and is due physiologically to increased contractions of the uterus occurring mainly on the first day of menstruation. Some women suffer from it at each period, some only when they are under emotional stress, still others are free from such complaints. The physical condition at times shows underdeveloped uterus and at times possibly insufficiency of progesterone (corpus luteum hormone) or excess of estrogen (follicular hormone)—but neither is constant or definite. Psychologically, there may be fear of the feminine role and particularly equating menstruation with being attacked and injured. The symptom often improves or disappears in the course of psychotherapy. Medicinal treatment consists mainly of analgesics and sedatives.

Experimental Investigations. The following experimental results have been obtained on animals and human beings: (1) If the gonads are removed operatively in either the male or the female animal, with rare exceptions the animal ceases to exhibit sexual activities. (2) The injection of hormones in adequate amounts restores sexual activity. Regardless of his original sex, the animal exhibits more readily the type of behavior which corresponds to the hormone injected. (Steinach, 1911.) However, under certain circumstances, the operated or unoperated animal may exhibit either type of behavior. (Ball, 1939.) (3) The injection of hormone into the healthy sexually functioning animal increases his or her sexual activity in a signifi-

cant percentage of experiments. (4) Passing homosexual activity, such as mounting another male or, conversely, lordosis and quivering of the ears if mounted, can be observed in male rats if they are hyperexcitable as a result of hormonal injections or if they were previously frustrated and no member of the opposite sex is available. (Beach, 1942.) (5) Some features of passing homosexual behavior can be observed in monkeys on the part of both the dominant and the submissive male or female. Thus the submissive male monkey may assume the female copulative position toward the dominant male, and the dominant male may mount the submissive male. (Maslow, 1936.) At times the female animal who is otherwise submissive to the sexually responsive male becomes dominant, and the sexually desirous male becomes submissive. (6) Dogs with experimental neurosis induced by the conditioning method may show frequent and almost constant erections reactive to the environment and particularly the specific signals formerly connected with food. Further, in normal dogs the conditioning environment has no effect upon the onset and duration of erection in response to normal sexual stimuli. Neurotic animals exhibit premature ejaculation in that the duration may be decreased to one-third of the animal's normal performance. (Gantt, 1942.) (7) Simultaneously with vasoconstriction and excessive perspiration in the extremities during emotional stress, the penis may become small, moist, and cool. (Mittelman, 1939.) This phenomenon of anxiety may interfere with adequate erection which is mediated mainly through increased blood-filling of the organ. (8) Erection has been observed in infants in response to nursing and frustration. (Halverson, 1940.) (9) The correlation between the sexual cycle and the psychological attitude has been investigated in women by simultaneous examination of vaginal smears, the daily measurement of the body temperature, and of the difference in the electric potentials between the tips of index finger on the one hand, and the productions of the subjects in psychoanalytic interviews on the other. The period in the sexual cycle can be determined by the shape and character of the epithelial cells and presence of leucocytes in the vaginal smear. (Papanikolau, Shorr, 1936.) There is a slight fall in body temperature and a rise in the difference between finger potentials corre-

sponding to the day of ovulation. When these changes were correlated with the psychoanalytic productions, the following was found: After menstruation, while estrogen follicular hormone predominates, there is a corresponding active heterosexual striving. After ovulation, the predominant attitude is self-admiration and self-satisfaction and desire to be taken care of. In the next phase, progesterone (the corpus luteum hormone) predominates. The corresponding attitude is passive receptivity and the desire for pregnancy. Just before menstruation, as the corpus luteum hormone declines, the predominant attitude is that of elimination; excretory dreams make their appearance. If the individual is afraid of any of these tendencies, particularly the heterosexual and the receptive trends, overt anxiety and nightmares or hostile counterattacking, violent castrative trends occur. (Benedek and Rubinstein, 1939.) There is an outburst of physical and mental activity before the onset of menstruation, coupled with high tension and irritability and preceded or accompanied by depression. Another high inactivity dominates the ovulative phase of the cycle, but this is free from tension and the mood is that of elation. (Altmann, Knowles, and Bull, 1941.)

Résumé. There is experimental evidence to demonstrate there is a correlation between the presence and the level of sex hormones and sexual and psychological activities. Sexual activity may change in correlation with alterations of life situations. The primary hormonal disturbances, such as menopause or hypogonadism, are correctable by the administration of the gonadal hormones together with psychotherapy. Disturbances in potency are accessible to psychotherapy.

REACTIONS IN WHICH DISTURBANCES OF THE EYES PREDOMINATE

A variety of eye complaints connected with personality disturbances may occur during life stresses: "spots before the eyes," pain during sustained eye work. Hysterical blindness has already been mentioned. Here one of the serious eye disturbances will be discussed.

Glaucoma. This condition is characterized by an increase in the intraocular pressure (pressure within the eyeball). If the condition is severe enough and lasts long, the individual may go blind as a result of the atrophy of the optic nerve. The condition, increasing in frequency

with advancing age, is probably due to disturbance in the blood vessels in the iris. The personality type and the conflict situation have not been investigated in detail, but the pressure usually rises during periods of worry, shame, and resentment. (Cobb, 1944.) The treatment consists of eye drops (eseron) which make the pupils contract and thus improve circulation. At times operation is necessary. Psychotherapy is helpful in addition.

REACTIONS IN WHICH DISTURBANCES OF THE JOINTS PREDOMINATE

Rheumatic Fever and Rheumatoid Arthritis. Rheumatic fever consists of acute inflammation of the joints, accompanied by redness, swelling, pain, and rise in temperature. The inflammation affects one joint after another. The heart may become affected, too, because of inflammation of its inner lining membrane. The attack may last several months. Rheumatoid arthritis at times starts the same way, but more frequently it develops gradually with pain and stiffness in some of the joints. As a rule the process does not wander from one joint to another in a single attack. The heart is very rarely affected. The rheumatic fever is undoubtedly an acute infectious disease caused by a streptococcus. The nature of the various forms of rheumatoid arthritis is not exactly known. It commonly develops between the ages of forty-five and sixty. Focal infections, e.g., infected tonsils or abscessed teeth, often play an important role. In some instances endocrine factors are likely to be present. The personality types vary. Common conflicts are rebellion against authority, with the consequent fear and guilt, and the desire to use the extremities for aggressive and sexual purposes. The diseased joints become the representatives of both the fulfillment of the forbidden desires and the punishment for them. Thus a vicious circle is set up. (Dunbar, 1945.) The physical treatment for rheumatoid arthritis consists of rest in bed and the administration of salicylates. In rheumatoid arthritis the treatment is the same in the acute period, with massage and the general raising of the patient's resistance in the chronic period. There are no psychosomatic experimental investigations of these disorders. It is likely, however, that vasoconstriction in the extremities plays an important role. (Mittelman and Wolff, 1939.) A further possibility is that the individ-

ual exposes himself to injurious situations—e.g., cold and damp without adequate clothing—as a result of rebellion or desire for self-injury.

REACTIONS IN WHICH ADDICTION TO DRUGS PREDOMINATES

The psychological reaction to chemical agents is determined by the special nature of the drugs, on the one hand, and the subject's personality, as well as immediate psychological constellation, on the other. (Mittelman, 1945.) Thus the psychological and psychosomatic effects of sodium amytal, alcohol, nitrous oxide, and marihuana may vary from subject to subject or from occasion to occasion in the same subject.

One may speak of addiction if the substance is used habitually—contrary to group habits—in relatively large quantities, and if it has deleterious effects. The most common substances thus used are alcohol, morphine (opium), cocaine, and marihuana (hashish). The most difficult ones to discontinue of these are morphine and cocaine. After prolonged use of drugs, characteristic psychotic reactions may develop.

The unconscious fears that are characteristic of addictions are of unbearable and catastrophic humiliation, particularly after failure, and complete submission and destruction, especially after the individual has sought relief from anxiety through homosexual submission.

The most commonly used intoxicant is alcohol. Its use has the following "ameliorative" effects: (1) consoling pleasure through the use of the mouth and the taste (Rado, 1932); (2) expression of hostility at sexual desires, during intoxication, which are ordinarily inhibited; (3) elation which helps the individual to forget his difficulties.

Treatment of moderate alcoholic addiction is psychotherapy. For severer alcoholic addiction the patient has to be in an institution. Use of sedatives and circulation stimulants may be necessary. Subsequent psychotherapy may prevent relapse.

Experimental Investigations. Experimental investigations are difficult to conduct because the social and psychological environments are hard to duplicate. Results of the association test will illustrate the effects of alcohol. The number of responses elicited in the same individual without alcohol was smaller, but the responses were of a distinctly superior quality, more logically

associated with the stimulus. For example: to the stimulus word *butter*, normally such response words are produced as *cheese*, *bread*, *yellow*; that is, words designating objects or qualities which in their origin are connected with the object designated by the stimulus word. After taking a glass or two of whiskey, the stimulus word *butter* may evoke such responses as *bitter*, *flutter*, *butterfly*; that is, words related to the sound and form of the stimulus word rather than to its meaning. These findings can be interpreted in the following two ways: (1) That alcohol diminishes the efficiency of the subjects in responding relevantly to a test of association. (2) That alcohol produces relaxation in the subjects; this is apparent in the ease of production of a larger number of "nonsense" responses. And, finally, some inhibited subjects respond freely and with relevance only with alcohol because of release from self-consciousness; this is apparent in the occasional individual who shows qualitatively improved production.

Cats with experimental neurosis induced by the conditioning method respond again adequately to stimuli after ingesting a small amount of alcohol. (Masserman, 1943.) This phenomenon may parallel the restorative effect mentioned in the human being. However, what obviously happens in alcoholism is this: With the quantity of alcohol increased, the repressed emotional disturbances overwhelm the subject.

Marihuana produces in small doses increased talkativeness, less inhibited motor behavior and speech if a conversation is kept up with the subject. Habitual users, however, after being given the same dose in a group experiment, sit quietly, get annoyed if somebody disturbs them, and laugh readily at jokes. In larger doses the drug often produces passing psychotic reactions: paranoid fear states and excitement.

Dogs have been experimentally addicted to morphine by regular injections. When the injections were discontinued, they exhibited similar symptoms to those exhibited by human beings during acute withdrawal: restlessness, salivation, diarrhea, circulatory disturbances, and collapse.

Résumé. Experimental and clinical evidence illustrates that the effect of drugs is determined by the nature of the drug and the subject's emotional reaction patterns. The initial use of the drug may be for restorative purposes with

quantities increased, and, with certain constellations, the repressed emotional forces dominate the picture. However, many of the drugs used habitually lead to addiction for biophysiological reasons also. In moderate alcoholism, ambulatory psychotherapy is often effective. Severe alcoholism, as well as morphine or cocaine addiction, requires institutional treatment.

REACTIONS IN WHICH DISTURBED FUNCTION OF THE THYROID GLAND PREDOMINATES

The psychological problems connected with hypothyroidism and hyperthyroidism have been discussed. Here a special syndrome will be presented.

Exophthalmic Goiter. Exophthalmic goiter is a condition in which there is enlargement of the thyroid gland and a considerably increased metabolism (up to +100), bulging of the eyes, trembling of the fingers, loss of weight, rapid heart rate, excessive perspiration, and other symptoms. The main psychological symptoms are due to an overfunctioning of the thyroid gland. This condition was found to be precipitated by reactions to life situations in fifty-six out of sixty unselected patients studied, i.e., in 93 per cent of the cases. (Mittelman and Conrad, 1933.) The most common conflict situation is guilt and fear of abandonment and of injury resulting from resentment over frustrated dependency longings. Three personality types are encountered: emotionally labile, overtly dependent and demanding; emotionally controlled, with high ideals of responsibility; and aggressive hard-driving, with high level of activity. The patient reacts to the thyrotoxic with fatigue, restlessness, and irritability; further either with self-condemnation and fear, or the illness is utilized for more open expression of hostility. Thus the final psychological symptoms are resultants of (1) original conflicts, (2) over-secretion of the thyroid gland, and (3) personality reactions to the toxic symptoms.

Treatment consisting of bedrest, sedatives, and diet is successful at times. Operative removal of a large part of the thyroid gland, after the toxic symptoms are reduced with iodine, is effective in about 92 per cent of the cases. Psychotherapy should always be given.

Experimental Investigations. It has been mentioned earlier (see "Hypnosis") that pulse rate and metabolism rise during induced fear reactions.

REACTIONS TO PHYSICAL ILLNESS

Convalescence. Psychogenic factors may play a role in the causation of even such illness as pneumonia (exposure) or fracture (reckless act). At other times, such illnesses have no psychogenic determinants. In either instance, however, physical illness represents a psychological problem as well, with which the individual has to cope. Mild irritability, anxiety or depression are not uncommon symptoms. Severe psychopathological reactions are at times precipitated by the occurrence of an illness or an operation. At other times, recovery from such illness as heart failure may be retarded because of emotional stress.

The patient's anxiety may be aroused because the illness threatens his bodily safety and because it incapacitates him temporarily or permanently for the work he is doing. This may, of course, further lead to financial worry. He may consider the illness or the operation, unconsciously, as a punishment for hostility or a dangerous fulfillment of passive, submissive, and masochistic strivings. Bedrest and care may gratify infantile dependency needs, but also stimulate excretory and perverse fantasies and thus arouse guilt and hurt self-esteem. Lastly, the confinement makes strivings of compelling force—e.g., for achievement, superiority—at least temporarily impossible. The patient may experience this as a threat of ultimate defeat and destruction. Recurrence of the same illness within six months or a year may mean to the patient inescapable doom.

The therapeutic conclusion is: The treating physician should be aware of the patient's restlessness or anxiety and discuss it with him at least briefly with adequate reassurance. Equally important is attention to the patient's family, which at times is the main factor in the emotional difficulties. (Mittelman and Richardson, 1944.) At times prolonged psychotherapy may be required.

Experimental Investigations. Four conscientious objectors volunteered to be confined to bed and be put in a cast for the study of the physiological effects of immobilization. They exhibited resentment, dependency longings, rising sexual tension, and difficulty in, preoccupation with, and embarrassment over excretory function. When the cast became recurrently painful and other feelings of discomfort recurred, they

experienced anxiety. Similar reactions occurred when pain and swelling appeared in knees or arches of their feet—structures in which they had suffered injuries or had difficulties with in adolescence. (Mittelman, Brodman, Weider, Wechsler, and Wolff, 1946.)

Résumé. Experimental and clinical investigations indicate that patients may react to physical illness and confinement with anxiety, hostility, increase in dependency needs, and passive masochistic strivings, together with increase in excretory and sexual conflicts leading to fear and guilt. The physical illness may aggravate or precipitate a psychopathological reaction.

REACTIONS IN WHICH EPILEPTIC PHENOMENA
PREDOMINATE

Epilepsy is characterized by attacks of unconsciousness, accompanied by violent convulsive contraction of the musculature of the body (grand mal). Less severe symptoms consist of disturbed consciousness in which the patient mumbles or engages in some stereotyped or unusual activity for which he has no recollection when adequate consciousness is regained (petit mal). In rarer instances, fugue states or violent rages occur with subsequent amnesia. The condition is at times symptomatic of some well-defined illness, e.g., tumor or syphilis of the brain. In a large proportion, no clearcut cause can be found (essential epilepsy). The electroencephalogram shows characteristic waves even between attacks or after forced breathing, namely, bursts of "spike and dome" or of high-amplitude, low-frequency waves. (Gibbs, Davis, and Lennot, 1935.)

The personality may be normal and when it is disturbed it is usually self-centered, either with irritability or the need to excel and shine. The meaning of the attack psychologically is violence, loss of control, as well as being overwhelmed. The common conflict situation is fear over the consequences of hostility. Chemical treatment is phenobarbital or allied drugs (dilantin), and psychotherapy is often effective in reducing the frequency of attacks.

PERSONALITY REACTIONS IN ORGANIC
BRAIN DAMAGE

The following principles apply to the conditions that will be discussed briefly below:

(1) The psychopathological reactions in the various conditions have many common fea-

tures, but it is equally true that each diagnostic category has fairly characteristic manifestations.

(2) The symptoms result not only from direct disturbance in function as a result of damaged structure, but also from total personality reactions to this disturbance.

(3) Differences in the reactions observed between various diagnostic categories are probably due (a) to the special nature of the disease process and (b) to differences in the structures which the processes usually attack.

(4) Differences between individual patients suffering from the same general illness are likely to be due to (a) differences in previous personality, (b) differences in the structures involved, and (c) differences in the rapidity of the disease process.

The causes of organic psychotic reactions are numerous. Among them are deterioration of the brain substance because of hardening of the arteries due to age; infections of the brain such as syphilis or encephalitis; infections in other parts of the body which are accompanied by fever, such as pneumonia, inflammation of the joints, typhoid fever; toxic substances, such as alcohol, opium, illuminating gas, lead; growths on the brain; injury to the brain; vitamin and glandular deficiency.

The chief symptoms of organic reactions—the chronic in particular—are: (1) Impairment of intellectual functions: comprehension, concentration, orientation, and memory for both recent and remote events. (2) Emotional instability: general irritability, laughter and weeping without adequate cause. (3) Changes in general conduct: carelessness in personal appearance, neglect of responsibilities, disturbance in moral conduct. The acute reaction is that of a delirium; the patient is disoriented, has illusions—i.e., misinterprets his perceptions—has difficulty in focusing his attention, hallucinates, and does not remember what has happened to him. He may be highly excited and have various emotions, particularly fear, or he may be emotionally dull. He cannot carry out certain functions or recognize objects adequately.

In both chronic and acute types the ability to copy simple configurations (Gestalt) is often seriously disturbed. In the following some of the conditions will be listed, together with the most common symptoms, in the fully developed stage, besides those already given:

Arteriosclerotic-Senile Reaction (Hardening of the Arteries of the Brain and Aging of the Brain Tissue). Wandering away from the home and getting lost, hoarding and hiding of small change or of worthless articles, and unsystematized delusion of persecution with hallucination and fear occur not infrequently. Many of these symptoms may represent projections of, or attempts to counteract the feelings of impairment, of age, and the fear of death and punishment for past aggressions.

General Paresis (Syphilis of the Brain). There are four main types characterized by: (1) Dementia—i.e., intellectual deterioration with contentment ("Feel as well as fish in water.") (2) Depression with anxiety and nihilistic delusions. ("My heart has been removed.") (3) Expansiveness with luxuriant delusions of grandeur. ("Own a thousand houses in New York.") (4) Agitation with great restlessness, continuous activity and combativeness. These may represent in part feelings of guilt and fear of punishment over sexual acts (depression) or remedial attempts against that and the failing functions (expansiveness). The treatment is either inoculation with malaria (Wagner-Jauregg, 1918) or the injection of an arsenical compound (tryparsamid).

Vitamin B Deficiencies—Pellagra. This disorder is characterized by inflammation accompanied by brown discoloration of the skin of the back of the hands, inflammation of the mouth, diarrhea, and nervous and mental changes. The latter are headache, dizziness, irritability, depression, and sleeplessness; in severer cases, anxiety, confusion, and delirium. The condition is due to deficiency of the vitamin B group, particularly of nicotinic acid. The treatment is administration of the vitamins.

Alcoholic Psychoses. 1. Delirium Tremens. Vivid visual hallucination of terrifying animals (snakes and rats), often with the fear of mutilation. These may represent in part symbols of the male organ and result from passive submissive homosexual strivings.

2. *Korsakoff Syndrome.* Characterized by (a) confabulation: the patient makes up stories that fill up the memory gaps; (b) occupational delirium, with visual and auditory hallucinations of a trivial, everyday nature (e.g., being engaged in workshop). Both of these symptoms may represent simple compensatory wishfulfillment, first by covering up the memory defect,

second by the patient "remembering" or hallucinating what he would like to be doing.

It is likely that alcoholic psychoses are partly caused by vitamin deficiencies.

Brain Tumors (New Growths). The psychological symptoms in brain tumors, like the physical symptoms, may be either general (due to increased intracranial pressure) or local (due to disturbance of special structures where the growth is located). The general symptoms are apathy and confusion.

As regards local symptoms: Visual hallucinations are most common if the tumor is located in the temporal or occipital lobe or in the thalamus. "Lilliputian" hallucinations are frequent in temporal lobe tumors: the patient sees small figures which he usually knows are not real.

Hallucinations of smell are most common when the tumor is localized in the temporal lobe or in the thalamus.

Hallucinations of taste are produced by tumors in the basal ganglia and the thalamus.

Jocularity is most common when the tumor is located in the thalamus or the striate body.

Irritability is most common when tumors involve the striate body on the left side of the brain.

Mental symptoms may appear long before local symptoms when the tumor is in the frontal lobe, because it may not extend back far enough to damage the motor area. (Gibbs.)

Head Injuries. The most common immediate effect of a severe blow to the head is a disturbance of consciousness. In some instances, the patient becomes delirious on regaining consciousness. The patient has an amnesia for the accident.

A common sequel is the so-called "post-concussion syndrome," characterized by headaches, dizziness, irritability, cold and clammy extremities, and anxiety dreams. These symptoms often disappear in a few weeks.

The chronic symptoms in general can be classified as psychotic reactions and changes in personality. The patient with a psychotic reaction may become apathetic and slow; he is often depressed and shows no initiative or is overactive, mildly elated, and witty.

Others may exhibit changes in personality: fatigability, inability to concentrate, irritability, and loss of ambition. Such patients tolerate alcohol badly; their reaction to it is sometimes

a terrific excitement during which they commit acts of violence.

Many of these reactions have in part the psychological implication of resentment over the violence and impairment suffered, fear of its recurrence or withdrawal from the environment.

The treatment after head injury is mainly bed rest and, in case of special complications, surgical measures. The handling of the patient is important on the one hand to keep some from resuming full activity too soon and others from becoming anxious and hypochondriacal. Here psychotherapy may be required. The psychotic reactions are slow in disappearing.

THERAPY

Psychotherapy. The dynamic aims of psychotherapy are: (1) increase in the patient's feelings of self-esteem and security; (2) relief of pent-up tensions such as anxiety, guilt, hostility; (3) increase in insight into his psychological difficulties; (4) increase in self-acceptance; and (5) increased integration and reaching toward positive goals resulting in improved relationships with people and improved ability to use various organ systems of the body for adequate function.

How does successful accomplishment of these goals help relieve psychosomatic disorders? It is clear from various topics previously discussed that (1) from the point of view of the total organism, emotional reactions represent both a psychological experience and an alteration in the function of the various organ systems; (2) reactions to disturbing life situations may be accompanied by disturbed function predominantly in one or another organ system of the individual; (3) the selection of the organ system affected is determined either by a primary pathology in the organ, as in epilepsy, or by illness of the organ system in the past history of the individual, as in asthma, or by special types of conflicts which are particularly suitably expressed through the affected organ system, as in circulatory disturbances of the extremities, or through a combination of all three; (4) since the organ system comes under special stress in connection with difficult life situations, a vicious circle is set up: the disturbance creates new anxiety and stress and preoccupation with the disturbance serves as a substitute for concern with the life situation; both reinforce the al-

tered function; (5) the patient's emotional conflicts are such that no adequate solution is possible. He can neither accept the situation nor act adequately to alter it. He has conflicting needs and impulses, thus there is continuous unresolved tension.

The patient's emotional disturbance has several sources: his disturbed relationship with other individuals, his conflicts within himself, and his memories. In psychotherapy, the pathogenic constellations are resolved. Through the relationship with the therapist, which is unique in its nature in that all subjects come up for discussion without disapproval and counter-attack, the patient's relationship with other individuals and with himself is gradually altered. His memories are brought into the open and the effects that his experiences had on his development are investigated. Thus, his conflicts are relieved, his evaluations of himself and of other people are improved, the displacements of emotional problems are undone, and the continuous state of tension is relieved. As a result he can handle the actual relationships with other individuals better, and he can use his organ systems adequately. In his relationship with the therapist, he reexperiences his past and current problems with a new and improved solution and he carries this improved solution into action in his daily existence.

Forms of Psychotherapy. The effect discussed above can be attained by a variety of procedures, the choice depending on the problems of the individual patient and the exigencies of the situation:

(1) *Interview Therapy.* The interviews are approximately of an hour's duration and usually take place once a week. The therapist encourages the patient, by sympathetic listening and skillful guidance, to talk about his problems. The symptoms are discussed only part of the time and then mainly in connection with the life situations in which they made or make their appearance. The patient's whole adjustment, day-to-day experiences, and past history are discussed. This type of therapy may be continued from a few weeks to a year or more.

In special situations, one to three interviews can be effective in relieving the patient's symptoms for a long period of time. This can be achieved particularly if the patient's problems

can be formulated to him clearly and he can arrive, with the help of the therapist, at an improved mode of living. (Meyer, 1906.)

(2) *Psychoanalysis.* The interviews are frequent, commonly five times a week. Free association, dream analysis, the patient's reactions to the therapist are utilized. Every significant topic comes up for discussion, not only because the patient brings them up, but also because the analyst has an opportunity to observe the patient's reactions from interview to interview in a subtle and detailed manner. Even when quick initial results are obtained in psychoanalytic treatment, the treatment continues for a long period because the patient's whole interlocking system of reaction patterns is to be disentangled and resynthesized. Analysis can succeed where the other procedures have failed and its ultimate results are more extensive. However, not all patients are analyzable. (Freud, 1906.)

Two other forms of psychotherapy, or their combination with chemotherapy, are less well standardized and are in limited use.

(3) *Hypnosis.* The patient is hypnotized by suggestions that he is drowsy, that he is getting relaxed and falling asleep. Some patients go into a deep trance, others exhibit varying degrees of hypnotic phenomena. Hypnotic technique can be used in connection with other forms of psychotherapy in the following ways: (a) suggestions are given to reinforce the therapeutic effect of the interviews; (b) memories are obtained from the patient in connection with his symptoms, then these memories are discussed in the waking state. This is possible only in deep hypnotic trance, whereas the first can be done even in superficial trance.

(4) *Group Therapy.* The group consists of three to ten patients, at times more. Some therapists prefer to have patients in the groups who all suffer from the same illness. Group therapy can be very factual and consist mainly of lectures explaining the emotional origin of the symptoms and the physiology of how the emotional reaction leads to disturbed organ function; but it can consist of the discussion of the intimate life problems of the subjects the same way as in individual therapy. Group therapy has one special therapeutic feature, namely it removes the feeling of uniqueness and that way relieves considerably the feeling of

inadequacy and anxiety from which the patients are suffering.

Combined Use of Psychotherapy and Chemotherapy. This combination is of two types: In one, the chemical agent is used to facilitate the psychotherapy. It is given during the psychotherapeutic session. In the other, the chemical agent, or at times physiotherapy, as in arthritis, is given along with psychotherapy.

Narcoanalysis. All the agents used to facilitate the psychotherapeutic procedure are sleep producing agents if given in larger amounts. They diminish, by the chemical route, self-control and self-criticism. As a result, the psychological material may be revealed more immediately and more directly and the experience may be relived in a more vivid fashion. The agents used most commonly are sodium amytal and sodium pentothal. Nitrous oxide and chloroform have also been used. The interview usually lasts an hour and the relief at times is almost immediate. At other times subsequent interviews without the use of the drug have to take place or the use of the drug has to be repeated. These chemical agents can be used to resolve difficult repressive situations during psychoanalytic treatment. (Kubie and Margolin, 1944.)

The Use of Chemical and Physical Agents Along with Psychotherapy. The various procedures in use have been discussed in connection with the various syndromes. The following additional remarks are in place: The exact relationship between the two procedures in the patient's emotional life has not been adequately worked out. On the one hand, the patient considers the use of the chemical agent as a kind of magic and then may expect the same kind of procedure of the psychotherapist to an intensified extent. On the other hand, the cutting of the vicious circle, as in hypoglycemic fatigue, makes the patient more accessible to psychotherapy. It also seems that, at least in some instances, patients who reject psychotherapy otherwise are willing eventually to enter it with the physician who handles both the physical and the psychological problems. (Daniels.)

Observation on Animals. Human psychopathology and therapy is more complex than that of any of the animals discussed, partly because of species difference and partly because stress situations saturate the patient's daily life over

long periods. However, the parallel with some therapeutic observations on animals made "neurotic" by the conditioning method is of interest. (1) Some animals recover in their general behavior and again react adequately to the conditioning stimulus if they spend a longer period away from the experimental environment. Some animals, however, do not recover for years and nearly all relapse quickly if they are exposed again to the stress situation. (Pavlov, 1904; Liddell, 1935; Gantt, 1942; Masserman, 1943.)

(2) Some dogs recover if sedative medication (bromides) is given to them regularly and some cats if they ingest alcohol regularly before being exposed to the normal stimulus.

(3) Some dogs, even while "neurotic," react adequately if the friendly experimenter stays in the experimental room; some cats, if the friendly experimenter pets them or if another "normal" cat is present in the enclosure. This parallels the supportive effect of the relationship with the therapist on the human patient.

INSULIN AND ELECTROSHOCK TREATMENT

The presentation of psychosomatics would be incomplete without a description of insulin and electroshock treatment. The procedures are used mainly in the treatment of severe psychotic conditions, namely schizophrenia and depressive reactions of the manic-depressive or the involutional type. In both of these conditions, there are relatively minor psychosomatic alterations, and the predominant symptomatology is in the psychological sphere. Briefly, in the schizophrenic reaction type, there is a flattening of the overt affectivity and a prevalence of bizarre reactions. Commonly four types are differentiated although the dividing line is not sharp and one form may change to the other. (1) *Simple type:* There is a gradual deterioration and flattening of interest and affect and finally of intelligence. There are no hallucinations or delusions, but the patient engages in silly preoccupations and gives irrational explanations for his activity. (2) *Paranoid type:* There are ideas of reference and influence and delusions of persecution; auditory hallucinations, including obscene words, predominate. (3) *Catatonic type:* There is an alternation between lack of external interest, to the point of stupor and waxy-flexibility, and periods of excitement

and rage. The first type of manifestation covers a much longer period. (4) *Hebephrenic type*: There is an abundance of involved and bizarre ideas and theories, often of a philosophical nature, together with delusions and hallucinations.

In psychotic depression there is a sad mood, slowness of thought and speech, lack of drive or, in the agitated type, there is, together with the depression, anxiety and motor restlessness such as wringing of hands.

Psychodynamically in schizophrenia, the feeling of being unloved, with a resultant withdrawing of interest from the world (narcissism) and a secondary attempt to reach out towards the world and express forbidden impulses and alter reality, predominate. In depression, disappointment in the world with the resultant intense hostility and guilt and finally the hostility turning in on one's self are the sequence of events.

In electroshock treatment, convulsions are produced. The patient's clothes are loosened and he is strapped to the couch by means of a specially constructed jacket in order to prevent his being injured during the convulsion. In some cases, sodium amylal is given before the shock in order to relax the patient. Electrodes are then placed on the patient's forehead. A dose of from 70 to 110 volts is given, usually for a period of 0.35 seconds. The treatment is given only as often as is necessary to keep the patient in an improved condition and lasts until recovery. Thus there is a great deal of variation in length and frequency of treatment from patient to patient.

Insulin is a product of the pancreas which lowers the blood sugar, which, in turn, affects the brain cells. Insulin is administered to the patient intramuscularly, starting with twenty units and increasing the dosage each day until coma is produced. When the proper amount of insulin is given, coma appears about three hours after the injection. The coma is allowed to last for an hour and a half when it is terminated by a nasal feeding of sugared tea. Where it is desired to terminate the coma rapidly, or when the nasal feeding is ineffective, the patient is given an injection of glucose. If the coma is not terminated at the proper time, convulsions, which are undesirable, may result. (Sakel, 1935.)

The effectiveness of these treatments is illustrated by the following figures: Electroshock is

effective about 85 per cent in depressions, insulin about 59 per cent in schizophrenia. The recovery rate in schizophrenia is about twice that obtained by usual hospital care. The ideal procedure is if treatment is supplemented or followed by psychotherapy, but the treatment can be effective even without that. The manner in which the treatment is effective is not known. The following assumptions are prevalent:

(1) Insulin and electroshock alter the brain metabolism, causing changes in oxidation, and producing either anoxemia or hyperoxemia.

(2) They act as sedatives reducing the overactivity of the nervous system and reducing the emotional pressure behind the symptoms.

(3) They stimulate the vegetative regulative centers, particularly the sympathetic division.

(4) Some organic changes are produced, especially in convulsive therapy, which imitate frontal lobotomy, interrupting the paths from the cerebral cortex to the thalamus and reducing the transmission of emotional impulses from one to the other.

(5) They act predominantly as a form of psychotherapy because the patient is given more attention and is always nursed back into active existence from the helpless state of unconsciousness.

Whichever of these assumptions is right, the patient becomes more accessible to contact with the outside world, particularly with people who look after him.

PSYCHOTHERAPY.—(Psychotherapy can be defined as the treatment of mental or physical disorder by using mental influences.)

Early Forms of Therapy. The origin of psychotherapy is ancient and shrouded in the obscurities of magic and miracle. The first physicians were the priest, the medicine man, the shaman, and their kind. Spells were cast, rites performed, incantations chanted, prayers said, and offerings made, to invoke the gods or the forces of nature so that health might be restored. Religion and healing were ever in close affinity. For example, in Egypt five thousand years before Christ, a princess was cured of demoniacal possession by the god Khons, according to a stone inscription. In Greece before the time of Hippocrates (d. 377 B.C.), who was the first Greek layman to become a professional physician, the medical centers were the temples of Aesculapius, god of medicine. There are descriptions of the elaborate procedures required of the sick before the oracle spoke in the inner temple: the bestowal of offerings, bathing in the fountains of the outer temple, and periods of probation devoted to public prayers and to listening to exhortations. In Europe in the Middle Ages treatment remained much the same, though religion had an altered nomenclature. Churches often had specialties. St. Roch, for instance, cured plague; St. Petronella, fevers; St. Mein, skin diseases. During this period a special power was attributed to kings in England and France, called "the king's touch," a curative for scrofula. Magic had by no means disappeared. Repeating the words "max, pax, et adimax" was believed to be the best remedy for hydrophobia; and "abracadabra" inscribed in a triangular pattern on an amulet worn by a patient with fever, was said to effect a cure promptly. Sir James Frazer in his classic *The Golden Bough* clarifies the distinction between magic and religion by pointing out that in religion man appeals to higher powers to intervene in his behalf, while in magical practices he tries to control the forces of nature directly. Some authorities see magic as an early attempt at true science. The medieval physician's prescriptions savor of magic, but at least he was endeavoring to utilize natural resources when he advised that a sow be tied to a fever patient's bed or that a wolf's right eye be ground up and applied to sore eyes.

Animal Magnetism. The doctrine of animal magnetism was a link between magical methods of treatment and scientific psychotherapy. Franz Anton Mesmer (1733-1815), a Viennese physician, is regarded as the founder of animal magnetism, though there were a number of other well-known magnetists, conspicuously William Maxwell, a Scottish physician. Mesmer described animal magnetism as a "universal fluid" but also as a kind of "impalpable gas." By means of this the planets could, he thought, influence man. He soon came to believe that the human will could set the fluid to work to cure disease, which he regarded as disharmony in the body. He supposed that the two sides of the body were opposite poles as in a magnet, and that to have health there must be a harmonious distribution of the fluid. Since he met with little encouragement in Germany or Switzerland, he went to Paris in 1778. Here he developed a unique clinic which was extraordinarily popular. The numerous patients were ushered into a darkened hall to the accompaniment of soft music. They then gathered around a low but expansive oaken tub, the famous *baquet*, which served as a storage battery for magnetism. The tub contained iron filings, bottles arranged symmetrically, and ground glass, all immersed in water. Jointed iron rods projected through the lid, and the patients applied the free ends to ailing parts of their bodies. The effects thus obtained were soon augmented by the presence of Mesmer himself, garbed in a silken robe and in his hand a long iron wand. Complete silence was enjoined as he moved slowly among the patients, fixing his eyes upon them, passing his hands over their bodies, and touching them with the iron wand. This treatment was likely to result in an ecstatic or convulsive "crisis," believed to be most beneficial. Many persons suffering from widely varied complaints were sure they were cured after two or three treatments. But Mesmer's remarkable success was finally impeded by two investigating commissions which discovered nothing more than "imagination" and "imitation" in magnetism. The consequent unfavorable reports, along with newspaper ridicule, turned popular opinion against him.

Magnetism, or mesmerism as it was often called, entered into a second phase around 1787. The beginning of this period is most often associated with the name of the Marquis de Puység-

gur, a disciple of Mesmer. Puységur was the first to take note of the trance. One time in endeavoring to magnetize a young shepherd, Puységur found that, instead of the mesmeric crisis, he had induced a sleep-like state in which the subject was highly suggestible. This condition was given the name "somnambulism." Workers in the field of magnetism now became convinced that their chief aim should be to produce somnambulists who were "lucid" or "ultralucid," i.e., who had the exalted, clairvoyant powers attributed to the state. Lucid somnambulists were called upon to treat the sick through supposedly superior understanding. The prescriptions were often fantastic, for example, one somnambulist repeatedly ordered a powder made from the callosities of horses' legs. Between 1813 and 1840 animal magnetism flourished exuberantly. Noted physicians and physiologists subscribed to the doctrine. There was much written about it, and numerous societies were formed for its promotion. Eventually the downfall of magnetism came through its inherent absurdities.

Hypnotism and Suggestion. Belief in animal magnetism gradually gave way to a more intelligent understanding of the facts. In France, during the second decade of the nineteenth century, the Abbé Faria showed by experiment that the real cause of the mesmeric trance lay within the hypnotized person himself. General Noizet, one of the Abbé's subjects was convinced that this was true and passed on the idea to a friend of his, Alexandre Bertrand, who is credited by some with being the founder of the theory of suggestion. However, Bertrand did not attract as much attention in this regard as did James Braid, an English physician. In 1841, the latter first investigated the trance and decided eventually that it was not due to any mysterious magnetic fluid. He coined the word "hypnotism" (from the Greek word *hypnos*, meaning sleep), and was probably the first to use the term "suggestion." Hypnotism attained fame especially as a means of achieving painless surgery. Esdaile, an English surgeon practicing in India, was a particularly noteworthy exponent of the method. He used the trance successfully in performing over a thousand operations, some three hundred of which were major ones. But the discovery of chloroform and ether around the middle of the century caused the eclipse of the hypnotic method,

since chemical anesthetics could be more readily employed. Hypnotism fell into disrepute and for about twenty years—between 1850 and 1870—was largely in the hands of charlatans.

The later development of hypnotism began with a controversy between two French schools of thought, one led by Liébeault and Bernheim in the little town of Nancy in eastern France and the other by Charcot in Paris. In 1864 Liébeault began to practice medicine in Nancy and with his peasant clientele often used hypnotism. He wrote a remarkable book on the subject. But little notice was paid to this until twenty years later when Bernheim, a professor in the local medical school, himself published an excellent work in which he called attention to Liébeault's contribution. They both found suggestion to be the essence of hypnotism. To them suggestion meant the immediate and uncritical acceptance of an idea in terms of action or belief. About 1880 Charcot, a distinguished Parisian neurologist, independently undertook to revive hypnotism and to study it carefully. In his zeal to be scientific he saw hypnosis (the trance state) only as a physiological phenomenon associated with hysteria. His experiments had serious errors, and he studied a very limited number of subjects, mainly three hysterical young women. He did not himself hypnotize but depended on his assistants to do this in preparation for his demonstrations. Because of his great reputation, his faulty conclusions were accepted for a time. But the point of view of the Nancy school eventually came to be accepted by scientific workers, even Charcot himself. After Charcot's death in 1893 Pierre Janet became the outstanding figure in French psychotherapy.

The work of the French in hypnotism had far-reaching influence. Many authorities in other parts of Europe and the rest of the world now gave serious attention to the subject and much was written on it. The period between 1883 and 1896 was one of very great activity along the line of suggestive therapeutics. All kinds of disorders were treated by hypnotic or waking suggestion; it was used not only as a curative for psychoneuroses and other more serious mental disturbances but also to mitigate the effects of organic lesions. Among the numerous writers in the field were: Forel in Switzerland; Moll in Germany; Van Eeden in Holland; Wetterstrand in Sweden; Bianchi in

Italy; Caryophyllis in Greece; Bechterew in Russia; and Moraga in South America. English-speaking countries were slower in adopting this type of therapy. However, Bramwell in England began in 1896 to publish accounts of his notable work. In the United States the investigations of G. Stanley Hall were followed at a later time by those of Boris Sidis and Morton Prince. But hypnotism had fallen into another decline. It was being criticized as producing only automatic response, and as difficult to use, even immoral.

About 1915 Janet in France predicted that hypnotism would be revived again. P. C. Young in the United States remarks on the truth of this prophecy in reviewing the literature on hypnotism in the *Psychological Bulletin* for May, 1931. He says further: "So many articles have been published [between January, 1926, and July, 1930], especially in German, that it will be impossible even to refer to them by title. . . . The reviewer has notes on 66 different books and 233 separate articles dealing entirely or clearly with hypnosis and suggestion. Of this number the Germans, Austrians, and Dutch are responsible for 15 books and 112 articles; the Americans for 17 books (including several texts on abnormal psychology) and 60 articles; the English for 16 books and 22 articles; the Russians and Poles for 5 books and 12 articles; the rest being scattered." In the February, 1941, issue of the *Psychological Bulletin* Young again reports on hypnotism, covering the nine-year period ending in 1939: he refers to "350 or so books and articles published during that time" on the subject.

In the thirty years since 1915 there has been careful and critical evaluation of hypnotism as well as its practical use. The American approach has differed from the European. In the United States the psychological laboratories have contributed numerous experimental studies and the literature has emphasized theory and explanation; in Europe interest has largely centered on application in medical clinics and investigation in physiological laboratories. The medical profession in the United States has been singularly indifferent to hypnotism, an attitude encouraged by popular prejudice. In Europe, on the other hand, medical publications and societies, especially those of Germany, have given full attention to this type of therapy. Its uses have been varied. It has been successfully em-

ployed as a means of diagnosis, especially to distinguish functional from organic disease; and as a method of treatment for (1) maladies which may have psychic components or origin, such as asthma, indigestion, and dermatological disturbances like warts and eczema; (2) certain mental disorders, including amnesia and many kinds of psychoneuroses; and (3) undesirable habits, for example, alcoholism, sex perversion, stuttering, etc. The European use of the trance to allay the pains of childbirth is especially noteworthy. Hypnotism has also proved valuable in operations in reducing the amount of anesthetic needed and as a general aid before and after surgery. It is too soon to say how much or how effectively the hypnotic method has been employed for war neuroses in the Second World War; but Eder, an English physician writing in regard to results with hypnotically treated patients during the First World War, states that "91.5 per cent of cases of war shock were cured by this method and 8.5 per cent improved." It must be remembered, however, that not every one is hypnotizable or easily hypnotized.

American psychologists have subjected the well-known phenomena of hypnotism to close scrutiny and rigorous experimental test. This field of investigation has attracted the attention of many able scientists, among the number C. L. Hull, P. C. Young, M. H. Erickson, A. F. Jenness, F. A. Pattie, and others. In his comprehensive book, *Hypnosis and Suggestibility*, Hull gives experimental findings on post-hypnotic suggestion and amnesia, improved memory, resistance to pain and fatigue, and other abilities reportedly superior during the trance. The majority of authorities hold to the idea that hypnosis is a manifestation of extreme suggestibility. That there exists a dissociation in Janet's sense of profound separation, is questioned. No informed student of the subject believes any longer that the hypnotist has any power over the subject other than through suggestion. Even *rapprochement*, the much-discussed accord between the hypnotized person and the hypnotist, turns out not to be an essential factor. Hull and others relate suggestion to learning, i.e., established association of words with the appropriate response produces subsequent reaction of the ideomotor type. Most of the American experimental work has only indirect bearing on therapeutic usage but some relevant

conclusions emerge. For example, it becomes clear from the studies of Kellogg and Patten that suggestions given to take effect post-hypnotically need to be repeated at sufficient intervals unless there are inevitable practice effects. R. R. Sears finds that hypnotically suggested anesthesia results in the disappearance of the obvious manifestations of pain, i.e., those under voluntary control, such as outcries and facial distortion, and semi-voluntary ones like altered respiration; but that pulse-rate is only reduced by a half to three quarters and the galvanic skin reaction by about 20 per cent. Even so, the use of hypnotism as an anesthetic is fully justified. More striking evidence of physiological changes of an involuntary sort comes from the study of brain potentials by Loomis, Harvey, and Hobart. With the subject's eyes fastened open by adhesive tape, these investigators suggested to him alternately—at 15 second intervals—that he could see and that he was blind. The suggestions of blindness always produced the typical "trains" that attend absence of vision. In the light of carefully controlled experiments like these, it is difficult to justify the contention of Pattie, Dorcus, and some others that a hypnotized person is merely acting or malingering.

Some of the reports from Europe regarding the physiological effects of hypnotic suggestion are indeed astonishing. Povorinskij and Finne caused blood sugar to increase by suggesting to the subject that he was eating honey; Shliffer counteracted the effects of adrenalin through suggestion; Platonow and Matskevich plied their subjects with enough alcohol to cause intoxication, but prevented it through suggestions that water was being drunk; Heilig and Hoff suggested liking or dislike for food and aroused appropriate stomach acidity as a consequence; Langheinrich suggested that his subjects were ingesting variously butter or bouillon and found congruous secretions when contents of the duodenum were examined; Marx as well as Heilig and Hoff were able to bring about changes in quantity and quality of urine secreted. Though not all investigators abroad or in this country get similar results, it is hard to avoid the conclusion that suggestion can markedly effect the autonomic nervous system. It also appears to be true that the specific suggestions must be in a form consistent with past associations of the subject; hence the utility of indirect suggestion. The successful experimenter

does not suggest suitable acidity of gastric secretion, but rather that the subject is eating a much-liked food, because in times past he has eaten this food with great relish and there has been the characteristic gastric secretion. In short, the words about eating the food have become conditioned stimuli, in Pavlov's sense, for certain physiological reactions. Many of the criticisms of experiments on hypnotized subjects are directed toward the absence of a control situation in which the same suggestions are given during a non-trance state. There are, however, actual experiments by Luckhardt and Johnston in which merely talking to an un-hypnotized person about food caused a rise in acidity and volume of digestive secretions similar to the effects of hypnotic hallucinations. Evidently suggestive effects are not limited to the trance.

The many variations and contradictions in the findings of experimenters in hypnotism deserve consideration. It is possible that the controls are at times inadequate. It is very certain that hypnotism is a far more complex matter than was first believed. Suggestions offered may not be properly understood by the subject, or unintentional suggestions which seriously alter results, may easily be conveyed. There not only appear to be different stages and kinds of hypnosis but many complicating factors, such as differences in personality, attitudes, and expectations on the part of the subject, and variations in method of induction on the part of the hypnotist. P. C. Young writing on hypnosis in 1941 says, "It seems a much more powerful reaction, much more potentially dangerous, and much more useful experimentally and therapeutically than was thought 10 years ago."

Autohypnotism, or self-hypnotism, is a variant that has attained some popularity recently in the eastern United States through the work of Andrew Salter of New York City. Ordinary non-trance suggestion and autosuggestion have been earnestly advocated, especially from about 1910 to 1920 by Coué and Baudouin in France. Their influence spread to other countries including the United States. In Europe especially up to the time of the Second World War this type of therapy attracted the active interest of a good many scientific experimenters and practicing physicians. Doctors everywhere make use of suggestion at times in authoritative commands, persuasive suggestions, impressive treat-

ment, placebos, or some other form. In general it can be said that ordinary suggestion has some advantages over hypnotic suggestion, but that statement also holds true in reverse.

Modern Religious Cures. Religion has never lost its effectiveness as a cure. Outstanding among modern European shrines is the miraculous spring at Lourdes in France. Since 1868 multitudes have gone there for relief from their ailments and many have departed cured. In eastern Canada at St. Anne de Beaupré, with its sacred finger bone of St. Anne, similar cures are obtained. Nor are these shrines isolated examples of present-day religious means to healing. It is quite safe to say that all over the world religion in one form or another has therapeutic uses.

A striking example is Christian Science, promulgated by Mrs. Mary Baker Eddy. This doctrine is a direct descendant of animal magnetism, which had quickly spread from France to America. Phineas Quimby, a New Englander, became a successful magnetizer, and through his treatment Mrs. Mary Baker Glover—later to become Mrs. Eddy—was cured of an hysterical paralysis. The two became great friends and after his death in 1866 she took over his manuscripts, which became the basis for her *Science and Health with Key to the Scriptures*. Later she repudiated this origin and declared Quimby's influence over her to have been one of "malicious animal magnetism." Her book is, however, essentially Quimby's teaching though replete with added rhetorical embellishment. From a therapeutic standpoint the significant idea is the denial of matter, hence of sickness, which is described as "error." Mrs. Eddy states that "God is All-in-all," that "nothing is matter." The way to cure illness is simply to deny its existence, since it is only a figment of "mortal mind." The healer, known as the practitioner, does not need any knowledge of medicine, surgery, or hygiene; he has merely to make clear to the patient that the illness, no matter what its nature, does not exist. There is no necessity for prophylactic measures or attention to diet or physical hygiene. "Animal magnetism" is singled out for special condemnation by Mrs. Eddy.

Christian Science has attained enormous popularity, and has a truly impressive number of adherents, not only in the United States but abroad. One of its several periodical publica-

tions is translated into six foreign languages and also into Braille. The large "Mother Church" in Boston, established by Mrs. Eddy in 1895, has been greatly added to; and there are numerous branch churches not only throughout this country but abroad as well. Christian Science has the advantages of methods of suggestion and reassurance. The patient is kept from fear and worry with consequent physical disturbance, and his body is thus prepared for normal functioning through inherent restorative properties. All religious treatment, if accepted wholeheartedly by the patient, provides a salutary feeling of security based on belief that the forces of the universe are supporting him. Janet points out that Christian Science marks a distinct advance over miraculous cures in that the human mind is recognized as a force for good or ill.

There have been other religious healing movements having more or less in common with Christian Science. Probably the best known are New Thought and the Emmanuel Movement. New Thought arose around the middle of the nineteenth century, and stressed a metaphysical idealism which showed similarities to New England transcendentalism, and also to the philosophy of Plato and the Vedanta of India. The aim of New Thought was to conquer human ills by establishing harmony with the Divine. Some of its exponents rather closely followed Christian Science in their directions for healing, but the greater number left room for hygiene and surgery, and even necessary medication. The Emmanuel Movement was begun in 1906 by Elwood Worcester and Samuel McComb, rectors of the Emmanuel Episcopal Church of Boston, in collaboration with some physicians. They sought to combine religion and medicine in a sensible eclectic therapy. Only functional disorders and bad habits, such as alcoholism, were treated. The movement spread to other churches and to other states and foreign countries. At the present time, however, New Thought and the Emmanuel Movement have been largely supplanted by less well known expressions of similar ideas, for example one doctrine called "Unity."

Allusion should be made to a very successful application of religion designated as the Fellowship of Alcoholics Anonymous, which has branches in many cities all over the United

States. It is an organization of reformed alcoholics, both men and women, who individually visit drunkards and persuade them to join. The fundamental tenet is the belief that God, as understood by each person, will supply the necessary strength for reform, if the need is admitted fully, restitution made to wronged persons, and a new way of life attempted. Members of Alcoholics Anonymous meet weekly and report their own experiences in a kind of public confession; they also have social meetings.

Psychoanalysis. Many psychiatrists believe psychoanalysis to be the one outstanding therapeutic method. Sigmund Freud (1856-1939) was the founder of the movement. He was born in Czechoslovakia of Jewish parentage, but spent most of his life in Vienna. As a medical student he became especially interested in neurology and later even studied with the great Charcot in Paris for a while. Freud was impressed by the use of hypnosis in the treatment of hysteria but not entirely satisfied with that method. With Josef Breuer, a Viennese physician, he began to combine hypnosis with "mental catharsis," a procedure in which the neurotic patient "talked out" his troubles and so found relief. Finally Freud abandoned hypnosis in favor of the catharsis method alone. The patient was asked to assume a reclining position, relax, and tell whatever came into his mind about himself and his troubles. If he stopped in his recountal, he was pressed to continue. Eventually free association came to be controlled somewhat by Freud's insistence that the associations concern the past, especially early childhood events. Dreams were also reported and served as a basis for further associations on the part of the patient but primarily as a fountainhead of information for Freud. In all this material he sought the complex, or disturbing idea, which he believed to be the cause of the patient's trouble. The true source had to be recognized and the early experience revived emotionally by the patient to effect a cure, and he was helped toward this by Freud's interpretation. Freud's book *The Interpretation of Dreams* was published in German in 1900. This was followed in 1904 by another of his earlier works, *Psychopathology in Everyday Life*, in which slips of tongue, pen, and memory, and all kinds of lapses were analyzed and shown to be indicative of complexes and a

kind of forgetting Freud explained as due to unconscious motivation.

By this time psychoanalysis had become not simply a method of treatment for neuroses, but an elaborate theory which its creator was continually expanding. The foundation is his belief in a subconscious mind, called by him "the Unconscious," which is far more important than the conscious mind. The theory of a subconscious mind is not original with Freud, but he added greatly to the then current concepts and gave special names and functions to subdivisions, such as the "Id," the mass of primitive impulses striving blindly for gratification, and the "Foreconscious," or "Preconscious," the part containing ideas which may be attended to. The keystone of his teachings is the importance of motivation through persisting desires repressed into the unconscious. He not only holds that all behavior is motivated by desires, but that nearly all of these are of a sexual nature. His followers claim that he uses the term "sex" in a very broad sense; Freud himself denies any indirectness of meaning. His main thesis in respect to therapeutics hinges on the dominance of sex and can be summed up in the postulate that neuroses have their beginning in repressed childhood sexuality. Such repression is also supposed to be normal with non-neurotic persons. According to Freud, all infants show sexuality in a "narcissism," or self-love, which finds gratification in various allegedly pleasurable experiences such as sucking, urinating, defecating, etc. In early childhood the "libido," or sex urge, comes to be directed toward the parent of the opposite sex, and the other parent is the object of murderous wishes. This is the general picture, but it is subject to modification by the child's tendency to identify himself with either parent. If normal development out of these early stages does not occur, then "fixations," "regressions," "infantilisms," or "the Oedipus complex" expressed in various neurotic symptoms, may result in later years. Freud conceives repressed desires as dramatically active. Childhood wishes live on in the unconscious as dynamic entities generating conflict. They constantly betray their presence in seemingly irrelevant acts as well as in dreams and in many other ways. It is in dreams that repressed desires can so easily break loose from the restraining force of "the Censor," the name Freud gives to our moral and social standards. Since

the desires are afraid of the Censor, they assume disguises and appear in symbolic form. Freud's writing is embellished with frequent personification, terms borrowed from Greek mythology, speculative interpretation akin to Hegelian dialectic, and numerous dichotomies, such as the libido and the ego, the ego and the id, the pleasure principle and the reality principle, the life instinct and the death instinct. This brief survey can only suggest faintly the richness of psychoanalysis, which Freud developed, remodeled, and wrote about constantly up to the time of his death.

It is not always easy to separate the facts basic to Freud's therapy from his theoretical assumptions. Take, for instance, two pillars of the therapy, resistance and transference. He believes that the early emotional experiences which cause complexes are deliberately repressed by the unconscious mind, and that to get relief the patient must relive them at the conscious level. "Resistance" is said to occur when the patient in the course of the psychoanalysis is unable or unwilling to tell everything concerning the disturbing situation. That this impasse is often reached is a well-known fact to therapists. But it is shifting from fact to theory to suppose, as does Freud, that an unconscious mind actively resists the memories and deliberately suppresses them. The American psychologist R. S. Woodworth points out that it is in keeping with our knowledge of memory and association to offer an explanation in terms of inadequacies of the association mechanism. As regards what Freud calls "transference," there is again a certain factual patient-doctor relationship to be accounted for. The patient often shows great admiration or love, or at times definite hate, for the analyst in the course of the treatment. Such reactions had disturbed and baffled Freud's earlier co-worker, Dr. Breuer. Freud, however, with his ever-ready genius for interpretation, regarded them as significant and useful. The emotion, according to him, is revived without a full renaissance of the whole childhood situation, therefore the emotion will center on the analyst as a substitute for the original person—probably the parent—who figured in the episode. The transference of attitude is believed to be a good thing temporarily, until the patient is able to carry on independently of the analyst. All this makes a very interesting theoretical

explanation, but there is no conclusive evidence that such transfer of emotional attitude actually takes place. The present emotion and the original one may not be one and the same. It is apparent that Freud fails to keep fact and interpretation separate.

In evaluating the general theory of psychoanalysis the more critically minded object to the hypothetical doctrine of the unconscious and the concept of ideas living on as ideas; to over-emphasis on sex, especially the supposition of infant sexuality; and to the many unproved assumptions and imaginative interpretations. It is contended that Freud made assertions for which there is wholly inadequate evidence. But he is highly commended, particularly by psychiatrists, for the invigorating freshness of his approach, his penetrating exploration of human motives, his emphasis on the importance of childhood in personality formation, and his psychogenic explanations introduced at a time when medicine was purely somatic and psychology had nothing to offer the troubled mind. Probably Freud is best regarded as an outstanding pioneer who recognized important aspects of psychotherapy but whose novel theories must inevitably be revised and amended.

From the standpoint of therapy, psychoanalysis offers the benefits of confessional methods in general. There is universal agreement on the wisdom of encouraging many disturbed patients to unburden themselves in this way. The "talking-out" method has a high place as a remedy and is used in some form by the great majority of psychotherapists. The most significant objection to Freudian analysis is that it does not go far enough, is a self-examination without sufficient constructiveness and upbuilding. There are other questionable aspects as well. It is doubtful whether incessant reminiscence in search of juvenile sex experience is wholesome or inspiring. Constant dwelling on one's self in the long process of psychoanalysis may develop or increase morbid egoism in the already self-centered neurotic. Freud's one notably constructive recommendation, viz., sublimation, or worthy substitute satisfaction for the libido, is allotted little emphasis in comparison with that given to explorations into the past. It has been pointed out that extreme attention to the past with little or no planning for the future may be a very unproductive pro-

cedure. Critics express grave doubt as to whether the interpretations given by the psychoanalysts are always valid. Analysts do not agree among themselves. The critics also give definite evidence that patients may sometimes be harmed by psychoanalysis or fail to get over their difficulties. Satisfactory results, it is said, may be due primarily to suggestion conveyed by the analyst in his impressive language, reassuring manner, etc. On the other hand psychoanalytic theory and practice are in many quarters accepted almost like a religious faith, arousing fervent enthusiasm and profound belief in their value. Psychoanalysts point to their successes and are convinced that their method is without question the best type of psychotherapy. They believe that psychoanalysis is much more than catharsis, is a "depth psychology" which uncovers the unconscious, explores the innermost recesses of the personality, and produces insight as a consequence of Freudian interpretation.

A favorable attitude toward psychoanalysis did not develop immediately. It was not until after 1900 that Freud had many followers. However, by 1911 psychoanalysis was well established. It has spread to various parts of the world, but has attained a more prominent place in the United States and Great Britain than elsewhere. Paul Schilder, a Viennese who later settled in New York, was the first to attempt a formulation of psychoanalytic psychiatry. The American physicians Jelliffe and William Alanson White became early proponents of this type of medical practice. Freud himself visited the United States in 1909 and gave a course of lectures at Clark University. But the person who has been more responsible than any one else for the diffusion of psychoanalysis in the United States is A. A. Brill, one of Freud's first pupils. Brill has translated most of Freud's work, and in 1911 founded the New York Psychoanalytical Society. In England Ernest Jones was one of the first to promulgate the new doctrine; Rivers was another of its earlier British advocates. American psychologists, with their dominant interest in experimental psychology, have not as a group shown the enthusiasm of the psychiatrists for psychoanalysis; English psychologists have given it a somewhat more cordial reception. At the present time psychoanalysis unquestionably has an outstanding position in medical psychotherapy. There are now a considerable number of jour-

nals devoted to psychoanalysis, an International Psychoanalytic Society with its own press, and, up to the time of the Second World War, active psychoanalytical societies in all the chief civilized countries. The literature of the movement is vast. Among those who have made distinctive supplementary clinical observations and expansions in theory are Abraham, Ferenczi, Rank, Ernest Jones, Alexander, Reik, Karen Horney, and Helene Deutsch. Abraham, Ferenczi, and Jones have made significant original contributions along the line of psychosexual genesis. Freud's theoretical investigations took him into many fields including history, literature, sociology, anthropology, religion, and art; and some of his disciples have undertaken similar excursions. For instance, Reik has interpreted psychoanalytically Goethe's romance with Friederika; and Abraham has made a detailed psychoanalytic study of the Egyptian King Amenhotep IV, whose reign around 3300 B.C. was shadowed by what we would now call his paranoid delusions. Otto Rank has introduced the concept of "the trauma of birth," i.e., the shock suffered by the infant when born. This experience is believed by Rank to be the greatest human frustration, though Freud himself does not attach as much importance to it. Two women psychologists, Helene Deutsch and Karen Horney, have presented their ideas as to the development of female sexuality, which are somewhat at variance with Freud's.

Horney has also disputed other and more basic Freudian hypotheses. She thinks that the patient's problems are to be explained more in terms of current attitudes in society and less in respect to childhood. According to her, sociological influences are really the most important source of unconscious conflict. Psychopathology, then, hinges on the helplessness, distress, hostility, and especially fear, thus engendered. She calls this emotional condition "basic anxiety." Because of feeling helpless, the individual is rendered less efficient, and because he is less efficient, he feels helpless; hence the "vicious circle," which Horney believes to be one of the most important elements in the persistence of pathological manifestations. Kardiner has a point of view similar in many respects. Part of the remedy, according to these analysts, should consist in changing the social order fundamentally. Freud, however, does not believe that man's aggressiveness can be altered

sufficiently to make possible a complete reconstruction of society. It should be noted that the general therapeutic procedure is the same in both approaches, though naturally the interpretations of the analyst are in terms of his particular point of view. The theories of Horney and Kardiner—particularly as expressed by the former in her books—have attracted a good deal of attention. Such variations in psychoanalytic concepts are an encouraging indication that psychoanalysis is not static, but has reached the wholesome stage when criticism is developing within the movement.

Psychoanalysis has practical limitations relative to time and cost. Statistics show that the average patient is treated an hour five or six days a week for from one to three years. At the usual charge of ten dollars a visit—the fee may be as much as twenty-five dollars—psychoanalysis in its usual form is clearly not for the poor. Certain other limitations are indicated by Maslow and Mittelman, strong advocates of psychoanalysis, who state: "The patient must have enough intelligence to realize that his suffering may have emotional causes, and to understand the analyst's explanations. Thus, feeble-minded people, for example, are not analyzable. The patient must have the 'right' type of psychological difficulty; in other words, not all types of psychological difficulties can be analyzed. Thus a patient with psychosis cannot be analyzed except in hospitals; and even here success is rather limited." The primary use of psychoanalysis is for the treatment of the milder mental disorders known as the psychoneuroses, or neuroses. The analytical procedure has, however, been used to a considerable extent in the study of those serious mental illnesses which we call functional psychoses. Moreover, Alexander, Dunbar, and Menninger have stressed the fact that there are psychogenic as well as somatogenic factors in organic disease; hence psychoanalysis can sometimes help an organic disorder. Mental aspects of many physical diseases have already been investigated from the psychoanalytic viewpoint, and detailed studies have been made of arterial hypertension, asthma, and some cardiac and endocrinological disorders. Mention should also be made of the intensive study of gastric neurosis by Franz Alexander, head of the Psychoanalytic Institute of Chicago. Naturally we cannot expect from psychoanalysis the startlingly immediate transformations of hypnotism

or religion, but analysts are convinced that their therapy is far more deep-reaching.

Outgrowths of Psychoanalysis. The two most widely known variants of psychoanalysis are Carl Jung's "analytical psychology" and Alfred Adler's "individual psychology," so named by their respective authors. Both Jung (b. 1875) and Adler (1870-1927) were early disciples of Freud, but in 1911 left his movement to develop their own theories. Jung, a Swiss whose activities have been carried on largely in Zurich, is usually considered the more profound of the two. In general therapeutic procedure they have a great deal in common with Freud, since all three use the "talking-out" method and study of dreams. There are marked divergences of theory, however.

In contrast to Freud, Jung lays no special emphasis on sex. For him, the libido is somewhat undifferentiated life-energy, which expresses itself in multitudinous ways, including food-getting, sex activities, and other instinctive reactions, and, more important still, distinctively human "creative strivings." The unconscious mind harbors not only repressed desires, but also inherited racial experience in the form of "primordial ideas," which constitute the psychic aspect of instinctive behavior. It may be noted that this racial, or collective, unconscious seems to be much like Freud's "Id." There are, however, distinct differences elsewhere in the views of the two men. Symbolism, for instance, is not the result of repression, according to Jung, but a natural manifestation of the survival of primitive thinking. The imagination is a limitless source of information as to personality, but fantasies concern the present life of the individual and the past of the race as well as repressed personal desires of childhood. In accounting for neuroses Jung finds the patient's present difficulty in adjusting to be the real cause, rather than the responses of early life, though these are predisposing causes. Jung begins therapy with a study of the way the patient has attacked his problem. Dreams are interpreted as betraying the attitude toward the difficulty. The aim of the analysis is to make clear to the patient his present primitive approach, to integrate the present and the past, and to redirect energy, especially unconscious energy, along worthy creative lines. Jung does not limit his "analytic psychology" to use solely with neurotics, but also employs the method

with normal individuals who have problems. We find much more that is constructive and inspiring in Jung's therapy than in that of Freud; in fact, the latter took exception to the moralizing of his former disciple. It must be admitted that the speculative theorizing in Jung's writings goes even further than Freud ventured, and has aroused among critics the accusation of mysticism in extreme. Jung's practical ability has been demonstrated, however, in his word-association test, a diagnostic device later standardized by Kent and Rosanoff. The test consists of a series of words, which are presented to the patient one at a time with the request that he respond by saying the first word he thinks of. Responses are carefully observed and various points noted, such as: the nature of the word given in reply; kind of repetition, if any; slowness, quickness, or unusualness of response; signs of emotion. Another contribution of Jung that pertains to diagnosis is his classification of human beings into types. While psychologists do not adhere to concepts of strict typal division, nevertheless Jung's terms "introvert" and "extrovert" have become well-established and useful descriptive terms. Jung has also made a brilliant study of the mental disorder at present generally known as schizophrenia. He has shown that there is meaning in the queer mental associations of patients suffering from this kind of insanity.

Adler, originally of Vienna, eventually developed his "individual psychology" in the United States. His essential point of difference with Freud lies in his conception of what constitutes the basic human drive. This Adler believes to be the ego motive, the desire to be important, to dominate, to have power. According to him, the human being primarily wants prestige, which is to be found in three chief fields: the social, the sexual, and the economic. The foundation of a neurosis is a feeling of inferiority. Adler makes much of "organ inferiority," i.e., physical defect or inadequacy, which he says arouses "the masculine protest." This drives the individual to "compensation." For example, Napoleon, with his organ inferiority of unusual shortness of stature, had inferiority feelings which led him to compensate through conquest of Europe. Compensation is obviously not limited to neurotics, and, from the standpoint of society, may take desirable or undesirable forms. Adler thinks that all children

develop inferiority feelings, just as Freud believes all have Oedipus complexes. Every person, Adler declares, evolves a "style of life," which is largely the result of his childhood relation with his family. Whether he was of rich or poor parents, the oldest or youngest in the family, a spoiled child, etc., are matters of importance in his future sexual, vocational, and other adjustments. The sex urge is not dominant, but has significant expression in accordance with the style of life adopted. Adler's therapeutic method is a modified form of psychoanalysis. Treatment begins with a study of the individual's style of life, which is sought first in his family situation of early years, then in his likes and dislikes, vocational aims and activities, reading interests, even in his posture when awake or asleep, and in all possible indicators. Like Freud, Adler studied the patient's dreams; but these are regarded as symbolizing his attitudes toward the future and not as expressing past desires now preserved in the unconscious mind. There is, in fact, no place in Adlerian psychology for a distinction between the conscious and the unconscious; the two are conceived as bound together. Resistance is recognized by Adler, but said to be due to the patient's dread of being cured lest his undertakings afterwards should bring failure. The neurotic is described as faced with the problem of evading reality and of finding difficulties in his own path, so that he himself and those around him will allow him a life of special privilege. The objective in therapy is recognition of the true situation, of the inferiority complex and compensatory efforts, with a view to improving the style of life, which, though thoroughly delineated in childhood, is subject to some modification. Adler's theory and methods have attracted many; but critics, particularly Freudian psychoanalysts, find "individual psychology" superficial. However, the practical wisdom in some of the concepts—like the "inferiority complex," for instance—has left an unmistakable impress on psychotherapy.

Two other of Freud's early followers, Otto Rank (b. 1884), mentioned before, and Wilhelm Stekel (1868–1940), should be referred to here. They are psychoanalytical in general procedure but definitely depart from orthodox Freudianism in theory. Stekel separated from the original movement at about the same time as did Jung and Adler. Stekel's work is rather eclectic, for

he accepts essential points from Jung, Adler, and others. However, he has produced original contributions as well. His book on the interpretation of dream symbolism is an example, and though Freud did not approve of all the meanings found, he regarded many as satisfactory. Rank's early concepts concerning birth trauma have been so greatly supplemented by new theories that he cannot now be classed as a Freudian psychoanalyst. He emphasizes the importance of the patient's response to the immediate situation, the need to live in the present. He does not look upon the individual as at the mercy of his primitive instincts to the same extent as does Freud. The human being, Rank holds, is a creature notably capable of independence and self-activity.

The influence of psychoanalysis is also evidenced in the development of certain allied techniques. An important one of these is the psychodrama of Joseph Moreno (b. 1892), a Viennese psychoanalyst who has established the Psychodramatic Institute at Beacon, New York. Much of Moreno's theory and interpretation is Freudian, but he has made additions in concept and terminology. His therapeutic procedure is distinctive, for he keeps to the original Greek principle of emotional catharsis through dramatic performance. The patient obtains relief by acting out his trouble. At the Psychodramatic Institute, Moreno has a small theater, the stage consisting of three concentric platforms slightly raised one above the other to form broad steps, which, along with a balcony at the back, afford ample acting area. Some member of the staff as a rule serves as planner and director of the performances, which are always structured on the patient's problem. The director generally provides the central idea, but characterization, dialogue, and action are left to the patient himself. He is a "spontaneity player," that is, he plays the part exactly as he wishes. He may also choose the other players from members of the staff or patients present. All patients may comment and make suggestions freely. Moreno has used the technique with certain psychotic cases taken individually, but much more often in the form of group therapy with psychoneurotics, problem children, and adults experiencing difficult life situations. There are at present two other well-known psychodramatic theaters: one at Bellevue Hospital in New York City; the other at St.

Elizabeth's Hospital in Washington, D. C. The latter institution is treating war neuroses by means of the psychodrama and reports striking success.

Other psychoanalytically grounded forms of group and individual therapy have emerged. For example, Paul Schilder (1886-1940) at Bellevue Hospital used to have groups of six or seven adults meet about once a week for discussion—with his guidance and supplementation—of the autobiography of a member of the group. Schilder has recorded that this brings many benefits for the patient, including lessened feeling of social isolation and greater self-revelation because of the stimulating presence of others with similar difficulties. Results are described as especially good in social and obsessional neuroses. Group therapy has been successfully used by other well-qualified persons in this country, prominent among whom are K. Lewin and F. Redl. A very recent report by D. A. Shaskan and Miriam Jolesch gives a promising picture of a trial of group therapy with war neurotics. S. R. Slavson uses group therapy with maladjusted children in New York City. D. M. Levy, also of New York, has developed a method of "release therapy" with children taken individually. Both Slavson and Levy depend almost entirely on catharsis effects. Interpretation by the therapist is altogether absent or at a minimum. The child is given play materials with which to do as he pleases. The therapist observes all the child does, but offers little or no interference even though behavior is destructive or offensive. In one technique devised to deal with sibling rivalry Levy provides metal dolls which can be dismembered. In such play situations children who are "rejected," "frustrated," or otherwise disturbed, are enabled to release pent-up emotion fully and thus recover affective balance. Levy finds that relatively few sessions are necessary if (1) the child's problem has been of short duration, (2) if the cause is no longer active, and (3) if the difficulty was the result of a specific cause, such as a particular fear situation. It should be noted that play techniques have both a diagnostic and therapeutic value, and have been as successful with groups as with individuals. While doll play and clay modeling are the most common forms of release therapy for children, there are also a number of other media of expression, such as drawing, "finger painting,"

soap carving, imaginative literary composition, poetry, puppet play, and dancing. Howard Potter and Louise Despert at the Psychiatric Institute in New York City have maladjusted children express themselves in retelling folk tales or other stories. Slavson describes another utilization of the release method in the form of semi-social group meetings of underprivileged mothers, the ultimate objective being to help the children through their mothers. All these forms of therapy rest on a background of Freudian interpretation.

Carl Rogers, an American psychologist, has recently formulated a variety of individual therapy, the counseling interview, which is a further derivative of psychoanalysis. Although his procedure is again essentially catharsis, it deviates in foundation from the analysis of Freud to a greater extent than any of the preceding variants. Rogers allies himself more with Otto Rank and Karen Horney. The present rather than the past is stressed. In Rogers' writings sex has no special prominence, and the unconscious is disregarded. When discussing the clinical treatment of children he shows the attitude of the psychologist rather than the psychiatrist. He says of orthodox psychoanalysis, "... the interpretation is not usually made on the simplest basis which will explain the facts but is made in terms of a preconceived ideology, frequently unverified, sometimes fantastic. . . . Psychoanalysis makes the belief of a particular school of thought the *sine qua non* of interpretation. . . . Where child analysis traces a behavior difficulty back to a definitely conditioning experience, it appears to be on more valid ground." In *Counseling and Psychotherapy* (the terms are used interchangeably) Rogers gives a clear account of his "nondirective" counseling technique as it is used for adults and adolescents. The client is encouraged to free and full expression of his feelings, emotions, and attitudes in regard to his problem. The counselor must not intrude his own views; simply accept, recognize, and clarify, at appropriate moments, what the client is expressing. This procedure "frees the client to look clearly at himself and his problems" so that "positive impulses which make for growth" follow inevitably, according to Rogers. Eventually there will be insight, acceptance of the self, and increasingly integrated positive action. It is important that the counselor avoid giving advice, for it

is to be a "client-centered" therapy and not "the counselor-knows-best" type of assistance; he must listen especially for feeling, rather than focus attention on content.

Rogers regards his method as a form of the "relationship therapy" earlier developed by Frederick Allen (at the Philadelphia Child Guidance Clinic), Jessie Taft, and others. "Relationship therapy" is so called because the relationship between the child or parent and the therapist is the prime feature. Rogers further explains it by saying that Freudian analysis emphasizes two factors, (1) insight through interpretation and (2) emotional experience, giving the first element a somewhat more important place; relationship therapy, on the other hand, makes the emotional aspect pre-eminent. It is of paramount importance in the latter method that the individual be allowed full freedom to express his feelings and to arrive at an understanding and acceptance of himself and his emotional attitudes in terms of present reality. Such realization, it is believed, will necessarily result in personality growth. Rogers admits that this kind of therapy relies heavily on the individual's capacity for growth and adjustment. Nevertheless he is convinced that his method is adapted to clinical, educational, industrial, and even military needs. Certainly he has performed a valuable service in presenting a concise, well-defined formulation of procedure, illustrated in a novel way by a complete phonographically recorded case history covering eight one-hour interviews.

Brief reference should be made to "hypnoanalysis," or "hypnalysis," a combination of hypnotism and psychoanalysis. Attention has already been called to the fact that Freud and Breuer were the first to use the two procedures together. This form of therapy is not extensively employed but has some authoritative supporters, such as Milton Erickson, psychiatrist at Eloise Hospital, Michigan, and the Menninger Clinic in Topeka, Kansas. R. M. Lindner, psychologist, has just written a book entitled *Rebel Without a Cause*, in which he gives a complete transcript of a forty-six-hour analysis of a young criminal at the Lewisburg (Pennsylvania) Penitentiary. After thirty-two psychoanalytic sessions Lindner hypnotized his subject in order to recover lost memories of infancy. Certain frightening circumstances were disclosed, and this information was used by Lindner as a guide in

subsequent waking analysis. He believes that hypnoanalysis is valuable especially because it takes less time than psychoanalysis alone.

Other Forms of Psychotherapy. At the beginning of the present century Paul Dubois (1848-1918) in Switzerland began to attract attention through his method of treating neurotics by means of a kind of moralizing appeal to reason, often referred to as persuasion or moralization. The patient is ordered to bed in a sanatorium and put on a milk diet as well for a week, though these measures are only preliminaries to the real treatment, namely, personal talks by the doctor. In these conversations the latter explains the functional nature of the ailment and the importance of changed attitudes and more uplifting thoughts, the aim being to develop self-mastery founded on an improved philosophy of life. Moral persuasion has been quite widely practiced by physicians in many countries, including the United States. Janet points out that the procedure is related to New Thought and the Emmanuel Movement. He believes that Dubois' method actually consists of more than reasoning, that there is a constellation of curative auxiliaries, including change of scene, rest, discipline, heightened self-esteem, suggestion, and the physician's prestige and example. A form of therapy having points in common with Dubois' method is that of German-born Fritz Kunkel, who is now established in the United States. His interviews with patients are also constructive and challenging, but the emphasis is on a religious altruism: religious "illumination" through self-examination is to lead to social consciousness.

Pierre Janet (b. 1859), already referred to several times, built his own concepts of psychotherapy on a prodigious knowledge of the whole field. His greatest contribution is in the sphere of the psychoneuroses, which he reclassified into hysteria and psychasthenia. He believes that psychoneurotic conditions are due to lowered mental tension. Normally a psychological synthesis exists, according to him, but this is broken when the individual loses mental energy, or "psychological force," because of disease, fatigue, emotion, or pubertal changes. In psychasthenia there is a generalized lowering of tension, hence a state of psychological depression. In hysteria the lessening of tension is localized, and the result is a dissociation, or disappearance of some specific function. Janet has always recognized

subconscious behavior, which he often considers under the head of "mental automatisms." In his vast clinical practice he has employed many methods, cleverly adapting procedure to the needs of the individual. The illustrious American William James was greatly attracted by Janet's work, and did much to bring it to the attention of psychologists in the United States. However, James' practical interests were not particularly in the pathological, but rather in helping normal persons toward more worthwhile living. In his famous essay *The Energies of Men* he asserts that human beings have much latent mental power which can be released through proper stimulation. Janet discusses at length "treatment by excitation," as he calls it, and lists numerous techniques for making dormant human resources available. Janet's success has been great, but his basic concepts have become overshadowed by the much more resplendent theories of Freud.

In the United States, Adolf Meyer (b. 1866) has long been referred to as the "dean of American psychiatry." He came to this country from Zurich in 1892, and held several important institutional positions before becoming professor of psychiatry at the Johns Hopkins University and director of the Henry Phipps Psychiatric Clinic of the Johns Hopkins Hospital, Baltimore. He retired from there in 1941 after thirty years of outstanding service. He has written comparatively little, but his influence and leadership in psychotherapeutics, the mental hygiene movement, and hospital organization have been very great. Many rate him as the greatest living psychiatrist. He constructed his "objective psychobiology" on an exceedingly broad framework of scientific and cultural knowledge, for his scholarly erudition encompassed the past and present developments of medicine and science in general and sociological and anthropological origins as well as the facts of medical procedure in hospitals for mental cases. With his students he insisted on an open-minded research attitude toward all methods, theories, and data, with freedom for drawing any justifiable conclusions. In application he has used whatever brings results. He believes that psychotherapy must be administered on the basis of an understanding of the reactions of the total personality—"therapy of the person," he sometimes terms it. There should be penetrating discernment of all the facts of the pa-

tient's life; then completely adequate remedial measures can be carried through.

Since Meyer's work was with psychotics in institutions, he was able to work out a reconstructive program which has set a high standard for other hospitals in the United States and abroad. After careful investigation and recording of the patient's life experiences, all physical aids of medication, hygiene, diet, massage, etc., are enlisted. The psychological aspect is equally stressed. Meyer has made an elaborate classification of psychopathological reactions and reaction types. Though his original terminology is formidable, his students have been inspired by his ideas; and in actual application his procedures are simple and sensible. Often the patient's psychosis rests on bad mental habits, Meyer believes, and retraining is in order. Hence the need for occupational, vocational, and recreational therapy, and other psychotherapeutic supplements of this kind. Meyer has described his procedure as "activity therapy." Psychoanalysis in the usual sense of the term is not employed, but the psychiatrist interviews each patient individually and makes use of all appropriate measures, such as discussion of the patient's life history, "talking-out," guidance, persuasion, reassurance, and desensitization, or the elimination of a problem by increasingly free discussion. The patients also often gain much from personal contacts with the games director, occupational therapist, physiotherapist, and others of the hospital personnel. Psychobiology has socializing as one of its major objectives, so provides opportunity for varied human relationships.

While Meyer has not subscribed to the extravagances of Freudianism, he believes that the procedure and more circumspect principles of psychoanalysis may sometimes throw light on the mental processes of the insane. Typically for Meyer, however, the avenue of approach is the conscious mind, rather than the unconscious. He has a program of treatment for psychotics, while Freud has a specific method for psychoneurotics. Where the latter would make an analysis, the former brings about a synthesis, a marshalling of all the patient's resources toward mental and physical health. Psychoanalysis and psychobiology rate as the two leading movements in psychotherapy today. From the standpoint of time, psychobiology is much more practicable since the average length of treatment is

six months, as against eighteen months for psychoanalysis. L. E. Hinsie states on the basis of figures from the Department of Mental Hygiene of New York State in 1934: "... the psychoanalyst treats five patients a year, while the psychobiologist is responsible for the care of about 176 in the same time." Though some efforts are being made to use shortened forms of psychoanalysis, it can rarely be used in any form as a curative for the major mental disorders. Hinsie says further: "... statistical reports lead to the impression that the percentage of improvements in the psychogenic patients treated under the psychobiological regime is approximately the same as that of a similar group treated by psychoanalysis."

Adjuncts to Psychotherapy. Adjuncts to psychotherapy, so much used by Adolf Meyer, need further comment. There are many procedures aside from drugs, surgery, and physiotherapy which have been used as aids toward achieving mental and physical health. The method of complete rest in bed began to be emphasized by Weir Mitchell in the United States in 1875, and subsequently had extensive vogue both here and in Europe. Reduction of activity instead of absolute rest, and suitable interpolation of rest periods have also had advocates. William James early recognized the psychological implications of muscular relaxation so earnestly recommended by Annie Payson Call in her widely read popular book; and Edmund Jacobson later developed a meticulous method of physical relaxation which he uses with psychoneurotic disorders. Isolation was employed by Philippe Pinel (1745-1826) in France as an important part of his famous reform in treatment of the insane. Charcot became an enthusiastic believer in isolation for hysterical persons. And in England the members of the Tuke family—William, Samuel, and Daniel—put the isolation method into practice in their York Retreat for the insane. Education and re-education, in the sense of training to improve mental performance or to cope with physical disability, are being used increasingly. About the middle of the nineteenth century, Seguin in France was one of the first to work out educational methods of this type for the feeble-minded. Charcot developed a method of re-education for hysterical paralytics: If the patient was incapable of any movement at all in the affected limb, the doctor would move the part himself while the para-

alyzed person concentrated on the resulting sensations; repetition of the procedure would eventually restore self-activity, but it was essential that the patient pay close attention throughout the training, describe the felt movement aloud, and himself perform the same movement with the unaffected other limb. To enhance awareness of progress Charcot provided his patients with some kind of gauge such as a very sensitive dynamometer to be held in the hand, or a movement indicator attached to the end of the finger. Re-education in various forms is now playing an important part in the rehabilitation of servicemen and war veterans. It may require a good deal of training to learn to substitute other parts of the body for a lost member, or to execute complicated and detailed movements with an artificial leg or arm, or to employ different sense organs for a missing one.

Occupational therapy is a noteworthy instrument for the re-education and exercise of muscles and nerves by means of tasks devised for the purpose. The field of occupational therapy, to which only brief reference can here be made, is broad and rapidly developing. Such arts and skills as painting, weaving, basket-making, working with wood, clay, and cement, and even upholstering, printing, shoe repairing, etc., are used to help restore mental health through the cultivation of satisfying interests. Patients in hospitals for the insane and other institutions often take pride in doing household tasks or gardening. Army and Navy hospitals provide, besides abundant entertainment, opportunity for studying high-school and college subjects and encourage vocationally aimed training and activities. Sanatoria for the tubercular, where rest is essential, find place for less vigorous types of activity, and in some institutions have bedside teachers of the school subjects from the early grades upward. Mental treatment may also take the form of recreation through music, motion pictures, and group activities such as games, sports, dancing, and social gatherings. Recommended reading along helpful lines is prescribed by some psychotherapists. All these therapeutic avenues have been demonstrated to have value in public and private institutions as well as with individuals treated in private practice.

Contributions of Psychologists. Up to the present time professional psychologists have had much less to offer psychotherapeutics than

have psychiatrists. The well-trained psychologist is predominantly an experimentalist and research worker. His chief contribution to therapy has been along diagnostic rather than remedial lines. Psychology has produced many and varied mental tests. There are tests of intelligence, interests, personality, social attitudes, vocational abilities, education, etc., etc., which have a very useful place in diagnosis. For instance, information as to the patient's level of intelligence may determine the kind of corrective therapy; or the need for institutionalization or further schooling; or advice as to future business or trade. Other kinds of test results may be similarly helpful.

It must be admitted that the two personality tests which have recently aroused the most enthusiasm as clinical assets are primarily the work of physicians. One is the "ink-blot test," which was devised by Rorschach in Switzerland as early as 1921, though it attracted attention tardily in the United States. The blots were first made by dropping ink on paper, which when pressed together gave a symmetrically shaped form. Now a series of ten standard cards is used, each with a carefully selected blot; some are colored. When a card is presented to the subject, he is asked to tell what he sees. The scoring is based on the nature of the associations suggested. If the subject sees human forms, he is believed to be interested in human beings; if he reads movement into the figure, this is supposed to indicate that he possesses creativity and a rich emotional life; if gray and black rather than color are the integrative agents that determine interpretation, the subject is suffering from an anxiety, etc. However, interrelationship of responses also figures conspicuously in scoring. Though psychologists have raised questions as to the validity of the Rorschach tester's deductions, the test has attained such popularity that it is now much used in both individual and group form. Another personality test of the same type is the thematic apperception test of H. A. Murray at Harvard. Series of photographs are presented to the subject with the explanation that this is to be a test of his creative imagination, that he is to make up a plot or story for each picture. Tests like this one, the Rorschach test, and the play techniques and psychodrama mentioned earlier are regarded as "projective," in that the individual reveals his inner life through some form

of expression. Besides being diagnostic and therapeutic, projective methods may serve as a gauge to determine progress of therapy.

Psychologists perform services having direct or indirect therapeutic value through many agencies, such as the courts, institutions for the feeble-minded or delinquent, orphanages, hospitals and hospital clinics, and especially child-guidance clinics. The non-directive counseling of the psychologist Carl Rogers, already described, was developed in a child-guidance clinic. The current work of psychologists in American hospitals is explained in the *Journal of Consulting Psychology*, 1944, No. 8. Where there are psychiatrists employed also, as in psychiatric and neurological hospitals, the psychologist gives mental tests to aid the psychiatrist in diagnosis, but the clinical interpretation of the psychologist is often an important contribution. In such organizations as the Henry Ford Hospital (general) in Detroit and the Children's Unit of Rockland State Hospital, New York, the psychologist is a therapist as well as a tester. In hospitals for the tubercular there is no fixed policy regarding psychological services. Private mental hospitals seldom employ psychologists. The armed forces of the Second World War have benefited greatly from the proficiency of psychologists attached to hospitals and other units. The major psychological activity for combat and training is mental testing and concerns selection and placement of men preponderantly; but the psychologist's duties in personnel and morale work, aviation psychology, etc., may be broadly clinical, and, to a limited extent, therapeutic.

Some psychologists maintain offices for private practice. These consulting psychologists are not generally psychoanalytical in their therapy,

but use the therapeutic interview for many purposes: (1) to investigate the needs of the client; (2) to provide him emotional release and relief; (3) to give fitting encouragement and reassurance, essential information or interpretive explanation, and common-sense advice and guidance if it is needed; and (4) to suggest desirable environmental changes, such as a better daily regime, family readjustments, and improvement along educational and vocational lines. One of the best-known consulting psychologists is Henry C. Link of New York City, who has done much to encourage a stimulating, sensible application of psychology. Some practicable therapeutic techniques are now emerging: for example, conditioning in various forms seems to have some utility; and emotional control and shock therapy effected in psychological ways appear promising. The Second World War has stimulated interest in therapeutic applications on the part of psychologists. Even hypnotism, so largely of experimental concern in the United States, has recently been turned more often to practical account.

length, or intelligence. The working hypothesis of the psychologist, on *a priori* grounds, should be that between groups which result from the use of one inherited trait or series of traits as criteria, there are no differences with respect to other inherited traits, unless and until relationships between the criterion and non-criterion traits have been demonstrated. It must be admitted that many investigations have been based upon the converse of this assumption; races have been grouped upon some arbitrary criterion; assumptions of inequality in non-criterion traits have been made; and investigations have aimed at the proof or disproof of these assumptions.

In the second place, many classifications have been based upon some measure of central tendency, to the whole or partial neglect of variability. Thus there tends to be set up a hypothetical "average individual" in each group, to be used as an arbitrary criterion for all other individuals. Since, however, every group exhibits variability, it may happen that relatively few individuals in that group will conform to the measurements of the "average individual." The errors involved would probably be of little importance if variabilities of traits were small. But this is not so. In a comparison, for instance, of the mean intelligence-test scores of Fijian and Indian children, it was found (92) that while the mean score of Indian children was statistically higher than that of the Fijian children, more than 30 per cent of the Fijian children equalled or exceeded the mean score of the Indian children. That the overlap in intelligence-test scores between whites and Negroes is too great to be disregarded is shown by the studies that have been made of gifted Negro children (131, 132). The anthropologist has not been unmindful of the fact that the criteria used have not always resulted in mutually exclusive categories, one of the marks of a good classificatory system. For instance, in his classification applied to certain groups in Europe, Hrdlicka (127) classified Germans as Celtic-Nordic-Slav-Baltic and Southern Russians as Slav-Finno-Ugrian-Celtic-Nordic-Tatar. The mixture of "race" and linguistic terms should be noted in this classification.

In the third place, classifications based upon one or more inherited criterion traits provide no warranty that all individuals in the group will exhibit identical or even similar behavior

in some non-related non-criterion trait. To assume such identity or similarity is to deny variability. The behavior of the individual is determined, not by the class into which he may be arbitrarily placed, but by the structure of the psychological field of which he is a part. Psychology still abounds in class analyses. It is sometimes stated that Germans are industrious, frugal and mystical; French are logical and sentimental; Nordics are domineering, self-reliant and courageous, Alpines are crafty, sullen and envious, while English lack a sense of humor. There are, undoubtedly, individuals in each class who exhibit the associated traits; not, however, because they belong to the class, but rather because of certain elements in the psychological field which are favorable to the development of such traits.

The use of terms involving a classificatory system is often essential for ease of communication and for purposes of discussion. In view of the nature of the material and the problems involved it is inevitable that classifications should arise in group psychology. Nevertheless, it is necessary to bear in mind that classifications are abstractions; that they involve variabilities with consequent overlappings; and that the task of describing human behavior does not end with classification.

II. THE PROBLEM OF SAMPLING

Human groups are different with respect to mental and physical traits. The casual observations of travelers as well as the investigations of anthropologists and psychologists have produced sufficient evidence for this statement. The problems facing the investigator of groups are those of determining qualitative and quantitative differences by objective methods, and of estimating the influences which have contributed to the development and maintenance of these differences. The greater number of group comparisons is made between infinite universes. Because of the difficulty or the impossibility of measuring large numbers it is necessary to draw samples from the universes to be compared. It is at this point that the psychologist encounters one of his greatest obstacles. Within reasonable limits, an investigator may define as he pleases the universe he wishes to consider; he may choose adult Polynesians in Hawaii; female Australian aborigines; Aleuts in Alaska, and so on. The drawing of the samples, however, must

conform to rules should the investigator wish to draw inferences about the defined universe from the sample he has observed. "The fundamental condition for random sampling is that each unit or individual of the defined universe must have an equal chance of being drawn, and, once drawn, no unit can be discarded without risk of bias." (93) If, for example, an investigator (4, 30, 31) decides to measure the intelligence of Aleutian children in Alaska and finds himself forced by weather conditions to make stops only at the most accessible villages; and if, in addition, some of the children to be tested refuse their co-operation because of shyness, then it can hardly be said that he has obtained a random sample of Aleuts. His results may be interesting, but his sampling does not warrant any conclusion being drawn with respect to the defined universe of Alaskan Aleuts. It is fair criticism to state that by far the large majority of racial comparisons have failed to pay their respects to this fundamental condition of sampling. The sum total for group psychology has been the accumulation of test results on samples, no one knows how far removed from random, from which no conclusion about the defined universe should ever have been drawn.

Three techniques of sampling deserve consideration by the psychologist. The commonest method, albeit that which has little in its favor save ease, is *accidental sampling*. As its name suggests, it is the method whereby units in the sample are drawn by accident,—ease of measurement, willingness, availability, and so on. It would be interesting to know how many samples, later to become the subject of controversy in racial and social psychology, should have been discarded out-of-hand on the basis of accidental sampling. The *method of random sampling* can be used where there exists a catalogued universe from which units may be drawn. Such a method requires the simple mechanical process of drawing every *n*th unit in the catalogue. Unfortunately the psychologist interested in comparing groups rarely has a catalogued universe. Since there is little certainty that every individual in an uncatalogued universe has an equal chance of being drawn the method of random sampling is of little value to the group psychologist. In the *stratified method* units are drawn from each of several strata in proportion to the number of individ-

uals in each universe stratum, the strata being decided upon beforehand by knowledge of existing variables that are in some manner relevant to the experimental variable. The advantage of stratified sampling lies in its greater precision; an advantage which is contingent, however, upon knowledge of variables which are likely to influence the experimental variable. There are but few examples in racial psychology of the use of stratified sampling, probably the best are those reported by Klineberg (70) and Franzblau (35). The sample having been drawn, the individuals tested and the results computed, there still remains the need for checking the representativeness of the sample before generalizations can be made. The only certain method of doing this is to compare the results with those of the universe. In group psychology this can rarely, if ever, be done because the universe values are unknown. Other statistical checks have been suggested but none appear to get rid of the bias which may have determined the selection of the original sample. What remains is the complete description of the sample in terms of the known variables of the universe from which it was drawn. Unless this be done, any critical evaluation of the results is impossible, and there certainly can be no justification for generalizations wider than is warranted by the measurement of the sample.

It has already been suggested that the only tenable hypothesis for the psychologist, on *a priori* grounds, is that there is no difference between the mean scores of abilities and traits of groups, other than between those criterion traits upon which the classification was made. This is in keeping with the null hypothesis which states that, since the real values of infinite universes can never be known, the only hypothesis which can be made is that between the means of compared groups there is no difference. True it is, that statistical treatment of the observed data may cause us to reject this hypothesis, in which case we have some justification for the assumption that some difference between means does exist.

III. THE PROBLEM OF TESTING

The comparison of human groups has involved two groups of measurements. On the one hand, there have been measurements of physical and psycho-physical traits; height,

weight, cranial measurements, hair texture, sensory acuity, reaction time, and so on. On the other hand, there have been measurements of mental traits and abilities, singly or in combination, and including general ability, specific abilities, interests, aptitude, and aspects of personality. Most of the former group are susceptible to direct measurement, and some of them, either singly or in combinations, have been used by anthropologists as criteria for segregations. Mental traits and abilities are difficult to measure in any culture. In the first place, there is not yet universal agreement as to the meaning of some of the terms used, e.g., intelligence, attitude and personality; secondly, the values obtained by present tests are the results, not of direct measurements, but of inference. The task becomes doubly difficult when attempts are made to compare the results obtained in one culture with those from another. It would be idle to allow measurement to wait upon universal agreement about definitions. There is common agreement that some units of behavior demand more "intelligence" than others; that some individuals succeed at tasks where others fail. The psychologist interested in the measurement of intelligence must rely upon indirect measurements. So, too, does the physicist. Temperature is measured by the length of a thread of mercury; air pressure by the movement of the surface of a partially evacuated container; electric current by its ability to turn an armature; sugar in solution by the rotation of a beam of light, and so on. The indirect and inferentially obtained values of the psychologist are justified by the methods of measurement used in other scientific disciplines.

The evaluation of intelligence, interests, personality and other psychological elements might be made by a complete lifetime study in one individual of all units of behavior related to these elements. Since, however, it is as impossible to observe all the units of behavior of the "behavior universe" of an individual or group of individuals as it is to measure all units in a population, recourse must be had to the measurement of samples of behavior. Such samples selected should be typical of the behavior universe, and, at the same time, should be sufficiently diverse to cover a wide range of the trait, ability or interest it is hoped to measure. Moreover, it must be emphasized that the sam-

ple selected as typical of one universe cannot, without observable evidence, be regarded as typical of any other universe.

Success in measurement in any field will depend, without adequate assumptive bases, upon happy accident. In most of the assumptions underlying the measurement of intelligence, there is the belief, implicit or explicit, that intelligence is commensurate with the ability of the individual to educe and to make use of relationships. It is clear that intelligence may function over widely differing elements in different cultures. So different may the elements be that one might speculate upon the shape of modern anthropology and psychology did these sciences have their origins in Samoa, Alaska or Bengal instead of in the Occident. Enough is known, for instance, of the cultural sanctions of many co-operative societies to state that some actions regarded as intelligent behavior in a competitive society would, if performed in a co-operative society, be regarded as stupid. Herein lies one of the obstacles in the pathway of the comparative psychologist. On what ground can he assume that a test valid in one behavior universe is equally valid in another? Even within the closest geographical area cultures show marked variation; Negroes and whites, even in the same towns, do not share comparable cultures. The first task of the group tester is to give evidence that the tests are applicable to the sample being tested; until this can be done, comparisons must be evaluated with caution.

Comparisons of intelligence test scores of children of two or more groups have been made using test material that has been standardized on but one of the groups (4). In these studies, the results of the tests on the groups not used in the standardization of the test have usually shown decreasing intelligence-test scores with an increase in age. It surely would not be contended seriously that the intelligence of the children of these groups does decrease with age; results of this kind point more likely either to faulty sampling or unsuitability of the test material at the higher age levels. They also indicate that the comparative psychologist who aims at comparing intelligence, interests, attitudes, personality, indeed any psychological trait, must develop tests so that none of the groups being compared will suffer any disadvantage because of the nature of the test material. It is very

doubtful if this has yet been done, and until it has been, the results are open to criticism. Many of the oft-quoted comparisons are of little value because the test materials and methods were alien to the groups being tested. The best tests will be those that are developed within and out of a knowledge of the culture in which they are to be used. For this reason, psychologists in the United States prefer the Stanford-Binet Scale to the Binet-Simon Scale.

It is unnecessary to enlarge upon the need for standardized test procedures when comparisons are being made. A knowledge of different cultures reveals the fact, however, that procedures in one culture are often impossible to reproduce in another. Time tests are likely to be unsuccessful in cultures which regard with scorn those tasks which take little time; the results of the "drawing-a-man" test are not likely to be useful in a community where one draws an enemy's picture in order to work black magic; nor can one be certain of age groupings in communities lacking birth registration, particularly when birthdays are not, as in Occidental communities, the excuses for annual festivities.

It would appear that, in some respects, the race psychologist has over-reached himself. Many of the comparisons of the past fifty years, it must be admitted, have been made with little knowledge of the culture of the group being measured, and, moreover, without much respect for methods of sampling and adequate statistical treatment. Of more scientific value would be a combined project undertaken by anthropologists and psychologists directed toward drawing a stratified sample of a single group, and the construction and administration of a test within that group. A few such studies co-operatively planned and carried to a successful conclusion would probably provide far more useful comparative material than has been gained from most of the studies of the past fifty years.

Other factors likely to vitiate comparisons will occur to the investigator who has worked in different cultures; the difficulty of securing rapport; the development of motivation, particularly in a co-operative society; the effect of chief-commoner relationships in communities where such ranks are inherited; the familiarity with the pencil-paper situation; the adequacy of two-dimensional pictorial representation of three-dimensional objects; the cultural influence

of magic; attitudes toward white men; influences of selective migration; the cultural effects of miscegenation, and so on. Unless relevant factors such as these are controlled, comparisons are of dubious value.

IV. CONCLUSION

A critical evaluation of the results of racial comparisons involving psychological tests must lead to the conclusion that most of the problems are still unsolved. True it is that there have been useful comparisons of physical traits. But with respect to those elements which have demanded indirect measurements, the results are inconclusive. It is not considered appropriate, therefore, to repeat here the methods and results of investigations which can be found in most textbooks; more to the point is the need for drawing attention to the criteria which should form the basis of critical evaluation of comparative studies.

1. *Race Classifications.*

- (a) The bases of grouping—national; linguistic; religious; or inherited physical traits.
- (b) The proportions of "pure" and "hybrid."

2. *Sampling Techniques.*

- (a) Method of sampling—accidental; random; or stratified.
- (b) Description of sample measured—control of relevant cultural variables.

3. *Test Materials.*

- (a) Method of selection of test items.
- (b) Validity of item analysis.
- (c) Relation of items to cultural situation.

4. *Administrative Factors.*

- (a) Control of physical elements—climate; economy; accessibility.
- (b) Control of cultural factors—socio-economics; language; education; factors specific to culture.
- (c) Control of psychological factors—motivation; rapport.

5. *Statistical Treatment.*

- (a) Sample—method of drawing and checking sample, use of statistical evaluation of sampling errors. Appropriate treatment of comparisons, correlations, analy-

sis of variance and co-variance where necessary.

Criticism of the results of "race" comparisons are fair and, in view of the conditions of measurement, inevitable. Until we know how to distinguish groups, and until more serious attempts are made to develop adequate tests, to control cultural and psychological variables, and to draw representative samples, we shall need to suspend judgment with respect to studies which have claimed to have proved "race" differences. The most satisfactory assumption, and the one which, on *a priori* grounds, should be the basis for future comparisons is that between human groups there are no differences with respect to inherited mental abilities.

RADIO RESEARCH.—A. *Introduction.* Research in the field of radio was from its beginnings 25 years ago affected by the fact that there was a market in which there was nothing tangible for sale. Unlike visual media, radio had only air time to sell and its ethereal character was obvious to any advertiser. It consequently behooved broadcasting companies to engage in research which would demonstrate to an advertiser that a program could reach listeners at a low unit cost. Early research in radio was thus more oriented in the direction of quantitative surveys that would measure the potential

size of the audience of a station than in the qualitative study of listeners' attitudes, their radio habits, program appeals, etc. This emphasis on quantitative measurement still prevails today. The buyer of radio time naturally wants to know how large a station's market is and what the opportunities are for increasing it.

From the point of view of applied psychology, the research possibilities in the field of radio are not only intensive but extremely manifold. The psychologist interested in market research finds this a most fruitful field. Sampling methods are basic to all kinds of surveys, whether of the radio audience, or of the sales effectiveness of radio advertising. Comparative studies of the audience and commercial effectiveness of radio versus other media offer real challenges to the development of adequately controlled techniques of fact-finding and measurement. The great role that radio communication can play and does play in the social and political life of the nation was earmarked by the election campaigns and "fireside chats" of the late Franklin Delano Roosevelt. Radio has rapidly become a chief, if not *the* chief, medium for the dissemination of news and analyses of current events.

The research possibilities of radio in education offer an attractive field of work for those concerned not only with adult education but also with classroom and formal school education. For the social psychologist the analysis of the social implications of radio broadcasting offers tremendous possibilities. Nor have they gone unnoticed in the role that radio has served in the war effort. The study of the listening habits and program preferences, of adults and children, of the sexes, of different educational, occupational and cultural groups represents a broad area of research that has implications both for radio and business as well as for social psychology. Finally, radio provides a fruitful field for qualitative research in the psychological appeal and effectiveness of different types of talent and different kinds of program ingredients. A picture of many of these aspects of radio research is provided by a perusal of the contents of the references cited at the end of this article.

Some aspects of these varied types of radio research are more psychological in character than others. In fact, it is difficult if not impossible to draw a sharp distinction between

psychological and non-psychological research in this field. The sampling and quantitative measurement of potential and of listening audiences are less psychological in their implications than the study of the attitudes and habits of listeners and non-listeners. There is, furthermore, one large area of radio research that apparently does not concern the psychologist, and that is technical, engineering research, as in radio electronics and radio operation. However, even here the separation is not complete. Although the technical production of radio operation is basically an engineering problem, the effectiveness or satisfactoriness of what machines will do needs to be judged from the behavior and reactions of listeners. This has been recognized as a basic research problem in the development of television.

In summarizing developments in radio research during the past 25 years—which is the age of standard broadcasting—we shall organize the different fields into the following three major areas:

- I. Quantitative Study of Audiences.
- II. Qualitative Study of Audiences and of Program Production.
- III. The Determination of the "Selling" Effectiveness of Radio.

The public itself is the chief source of data for the problems of all of these areas. The following types of devices are employed to obtain the research data:

1. Interviews: (a) by direct contact in the home; (b) by telephone.
2. Mail response: (a) unsolicited; (b) to broadcast announcements of free offers, contests or special appeals; (c) to systematic samples by ballots or questionnaires.
3. Audimeter records of the use (and non-use) of radios in homes for stations, over a continuous calendar period.
4. Polygraph records of listeners' attitudes towards the detailed content of programs.

Generally, radio research attempts to determine how many people listen, when they listen, to what they listen, who they are, how they listen, where they listen, as well as to why they listen; and, finally, how they are influenced by what they hear. All of these research questions are basically psychological ones. Each is concerned with human behavior. However, before we undertake to describe the application of re-

search methods to the study of these many problems, it will be well to have a picture of what the field of radio as a commercial market, as well as an educational and entertainment medium, is today.

JOHN GRAY PEATMAN,
College of the City of New York

B. *The Radio Market.* Within the span of two decades radio has become one of the chief advertising mediums in our national economy. It has in many ways eclipsed its closest rival in the entertainment field, the motion picture industry. More than 925 stations are at present engaged in standard A. M. broadcasting to the public in the United States. A great majority of these stations are affiliated with a national network organization: The National Broadcasting Co., organized in 1926; The Columbia Broadcasting System, 1927; The Mutual Broadcasting System, 1934; and The American Broadcasting Co., formerly the Blue Network, 1942. Once television, particularly color television, has been satisfactorily developed—this is not the place to predict what will happen—there is little question that this new mode of communication will be an even greater advertising and entertainment medium than is radio today. Radio, in the dissemination of news and comments on current events, the discussion of national and local problems, has also become a major medium of information and informal education. However, from the point of view of formal education, radio has not played the role in our public educational system that it might well have served. Television may come to play a greater role in the lives of growing Americans in this regard. In view of the great value of visual aids in instruction, television should be able to do on a far greater scale what educational movies have attempted to do in the classroom.

Radio in the United States has, on the whole, been operated in the public interest, with the operating income of a station generally dependent upon advertising. Broadcasting is part of our national inheritance. The right of a station to go on the air with a transmitter is a privilege granted as a license by the Federal government. This privilege is contingent upon the provision that a station operate in the "public interest, convenience and necessity." However, the Federal Communications Commission

has no right of censorship over the content of programs. The Congressional Communications Act of 1934 is explicit on this point: "No regulation or condition shall be promulgated or fixed by the Commission which shall interfere with the right of free speech . . ." Broadcasters have worked out their own system of self-regulation and self-control. They are sensitive to public opinion: a housecleaning of programs and commercials in some quarters is currently in progress. By contrast with radio in totalitarian countries, broadcasting in the United States is a servant of the public. And it is free.

The first official count of radio homes by states and counties was made by the United States Census Bureau in 1930. In 1935 an official committee on radio research was organized under the auspices of the Association of National Advertisers, the American Association of Advertising Agencies and the National Association of Broadcasters. In one of its first releases this committee undertook to describe the number and distribution of radios as of January, 1936. The report indicated a total at that time of nearly 23,000,000 radio homes. By 1940, according to the United States Census of that year, the number of radio homes had increased to nearly 29,000,000. By 1945 more than 33,100,000 homes (more than 90 per cent of all homes) were estimated by the National Association of Broadcasters to be equipped with one or more radio sets, distributed as follows: 95 per cent of all homes in cities of over 100,000; 94 per cent for cities of from 2,500 to 100,000; 89 per cent of rural non-farm homes and 88 per cent of farm homes. By economic levels, practically 100 per cent of all A, B, and C income-group homes had radios (42 per cent of the total); 93 per cent of all D homes (37 per cent of the total) and 78 per cent of all E homes (21 per cent of the total) had radios. An additional 8,750,000 were estimated to be in automobiles, and with the duplications of radio sets in homes and radios in public places, hospitals, etc., about 60,000,000 radio sets were estimated to be in use that year. This tremendous distribution of radios in the United States, made possible by the mass production of receiving sets at a low cost, means that practically everyone today has access to a radio. Radio is the ubiquitous phenomenon of communication born only yesterday.

The first commercial program was broadcast

on September 7, 1922 over Station WEAf in New York; the "product" was real estate and the sponsor paid \$100 for 10 minutes of time. Radio developed rapidly as an advertising medium; gross billings for radio advertising increased from about \$5,000,000 in 1927 and nearly \$90,000,000 in 1935 to about \$400,000,000 in 1944. National network advertising alone accounted for nearly \$200,000,000 of this total in 1944. Over \$100,000,000 went for local station advertising; another \$93,000,000 to national and regional non-network advertising and \$7,500,000 to regional network advertising. In the national field of radio advertising, drugs and toilet goods led all product groups with a total of more than \$53,000,000, or nearly 28 per cent of the total gross billings. More than \$42,000,000, or about 22 per cent, was spent in the advertising of foods and food beverages and nearly \$20,000,000, or 10 per cent, for the advertising of cigars, cigarettes and tobacco. The fourth product group was laundry soaps and household supplies, which accounted for another \$12,000,000. Fifth was confectionery and soft drink products, with more than \$10,000,000. These five categories of products, it will be noted, accounted for nearly \$140,000,000 of radio advertising on national networks—70 per cent of the total—in 1944.

An analysis made by the research department of the Columbia Broadcasting System of media expenditures for 1943 by one hundred leading national advertisers showed radio definitely in the lead with \$126,000,000 spent for network advertising. Magazine advertising was second, with a total of \$103,000,000 and newspaper advertising was third with about \$61,000,000.

A further index to the economic aspects of radio is given by radio net time sales. In 1935, about \$80,000,000 was spent for radio time. This figure reached nearly \$300,000,000 by 1944.

Finally, the over-all estimate of net costs for radio advertising (including time and talent) during 1944 is placed by L. D. H. Weld as 400 million dollars. His total estimate of net costs for all media is placed at 2 billion, 270 million dollars. Newspaper advertising led the field with a total of 645 million. But radio was second. Direct mail advertising accounted for 300 million, and general magazine advertising was fourth with 285 million.

From the point of view of employment, radio

represents the creation of thousands of jobs that did not replace work in any other field. It, and now television, are new industries. They have given birth to new professions. In 1941, more than a quarter of a million people were directly employed in the radio industry, exclusive of part-time employees and artists.

If we ask what kind of programs radio gives the public, we obtain the following picture,—based on an analysis of commercial network time for the winter season of 1943-4 made by the Cooperative Analysis of Broadcasting. Of daytime commercial programs on the networks, 57 per cent of the time was given to serial drama, about 11 per cent to news and talks, nearly 9 per cent to variety shows, about 7 per cent to drama, nearly 5 per cent to children's programs and between 4 per cent and 5 per cent to classical and semi-classical music. The remainder of the commercial time was given to audience participation shows and non-classical music.

For night-time, commercial network programs, 28 per cent of the time was given to drama, 20 per cent to variety shows, 18 per cent to commentators, news and talks, nearly 13 per cent to popular music and about 10 per cent to audience participation shows. The remainder of the time was accounted for by other types of music and by children's programs.

The picture of broadcasting for sustaining network programs and for local stations is somewhat different from the preceding distribution of network commercial time. Thus a much greater proportion of popular music is used on sustaining programs and by local stations. An analysis by the writer of the radio week, as monitored from 8:00 A.M. to 1:00 A.M. daily, for all broadcasts of the four New York outlets of the four networks, revealed for four sample weeks of 1941 and 1942 that approximately one-third of the total broadcasting time for this period was given to popular music. A similar analysis was made of all programs broadcast from 5:00 P.M. to 1:00 A.M. over three independent stations in New York City. This revealed that more than one-half of their total time was given to popular music. These figures suggest what has for years been fairly typical of radio broadcasting—popular music is the great "filler-in," with recordings and transcriptions playing a dominant role on

local stations throughout the country. This trend has no doubt passed its peak on the networks and is probably at its peak for local stations. This is the case because of the increasingly wider recognition of the value, not only to the advertiser but to the radio station as well, of the development of programs that have an individual character and appeal of their own.

The radio market is thus seen to be a broad domain in which radio sets are available in practically all homes of the United States, millions of dollars are spent by advertisers for this medium, and a variety of program material is available for listening. What about listening? Radio has, of course, gone a long way from those days in the early 20's when John Smith with a crystal set would emerge for work in the mornings, bleary-eyed but happy.

In a national survey made by Elmo Roper for the Columbia Broadcasting System in 1940, it was found that one once-a-week program was heard three times a month by an estimated audience of 50,000,000 men and women. A total of five CBS programs were estimated to have monthly audiences of over 40,000,000. The average CBS program was estimated to reach nearly one-third of all adult men and all adult women, at least once a month. These figures are obviously to be compared with the circulation of some of our leading national magazines. At that time, Life Magazine estimated itself to have a circulation for a single issue in a month of 15 million adult readers. The average circulation of the 1,877 daily newspapers in 1940 is reported as slightly in excess of 41 million copies.

The preceding figures are for only one national network and do not of course include listening to other stations. It is estimated today that about 90 per cent of all radio homes tune in to a station at least once a day.

The regular surveys of national listening in telephone homes of urban areas, made by the C. E. Hooper organization, reveal a marked similarity of trend in evening listening and daytime listening during the past several years. Thus, during the winter months an average of about one-third of these radio homes is estimated to be tuned in to programs each evening. During the summer months the percentage of radio homes listening declines to about 20 per cent. During the daytime period the listening is less and so is the seasonal fluctuation, with

an average of about one-sixth listening during the winter months and about one-seventh tuned in during the summer months.

The greatest U. S. listening audience for a radio broadcast to date was the one that the late President Roosevelt made to the nation on December 9th, 1941, at the time of Pearl Harbor. Four-fifths of the nation's homes were estimated by C. E. Hooper to have tuned in—an audience of more than 60,000,000 listeners. On election night in 1944, listening for a whole evening period was at an all-time high. More than one-half of the nation's radio homes were estimated to be tuned in sometime during the period from 7:00 P.M. to 10:30 P.M., EWT. This audience, interestingly enough, was 55 per cent greater than for a usual Tuesday evening. President Truman's V-E Day announcement on Tuesday morning of May 8th, 1945, was heard, according to the C. E. Hooper surveys, by 63 per cent of the nation's radio homes, a figure nearly 400 per cent higher than that for the same time period of Tuesday the month before.

These instances of unusually great audiences point to one of the fundamental facts of radio, namely that the proportion of people in their homes *available* for listening is always considerably greater than the proportion of those actually listening. The proportion of homes with at least one person available for listening, whether or not the radio is actually tuned in to a station, averages about 75 per cent for both day and evening periods, for winter and for summer, with the peak of availability reaching more than 80 per cent during the evening periods of the winter months.

Thus, people listen, but who are they? What are they like? Why do they listen? What do they do while they are listening? And, finally, how are they influenced by their listening? Are they, for example, influenced into buying the products advertised? These are the basic kinds of research questions that have developed out of the radio market. In the following sections we shall describe the chief methods that have been developed and are in use for getting the answers.

C. Quantitative Study of Radio Audiences. The chief types of quantitative audience research that have been developed during the past two decades have been oriented to determine

how many people listen, when they listen, and to what they listen, as follows:

(A) The size of the *potential* audience of a station or network,

(B) The audience *coverage* or *circulation* of a station or network, and

(C) The size of the *listening audience* of a station or network, program or time period.

Sampling, it should be observed, is inherent in nearly all types of audience research. Unlike newspaper and magazine media, which can measure their circulation in the number of copies delivered or sold, radio has to go out into the homes of the nation. A census (*complete* count or measurement) of a population is costly. In general, for radio research as for most market research, the procedure of sampling a population is indispensable to the methods used. When a sample is properly designed according to the principle of randomization or of stratified-randomization, the results can yield satisfactory answers about the population being investigated. A sample yields an *estimate* of an audience, or of whatever is being studied. All such estimates are therefore subject to error and these should always be taken into consideration in the evaluation and interpretation of results.

A. RADIO'S POTENTIAL AUDIENCE

We have seen that radio in its beginning had nothing tangible to sell and that it turned to quantitative audience research in order to have something besides sound effects to exchange for the advertiser's money.

Research for the potential audience was developed first and continues to yield the prize sales argument of many stations, especially in the form of potential listeners per advertising dollar. The methods used, however, have varied considerably, oftentimes to the despair of agencies and advertisers.

Maps of a Station's Potential Audience, Based On the Signal Strength of a Station and Census Figures of Radio Homes. In the early 20's, estimates (in the form of a guess) of the audience potential of a station were sometimes made by a crude map-and-compass method. The station would be located in the center of a circle drawn on a map with a radius of 50 miles, or 100 miles, or according to the guess made. Since then, maps of potential audience have generally been developed on the basis of standards set by the Federal Communications

Commission and on computations made by accepted engineering consultants. A unit of a half millivolt has been employed as a satisfactory signal strength. The measure of potential audience is then set up according to the number of radio homes in a county or other geographical sub-division for the area reached by a station.

Such a measure as signal strength obviously gives no estimate about a station's *listening* audience. It is an engineering rather than psychological approach to the problem of audience potential. It simply lays out the geographical area that can be reached by a station with a signal clear enough for satisfactory reception under normal circumstances. The potential audience of the station, as thus determined, will vary from day time to night time and consequently two sets of maps are usually made in order to distinguish between these two periods of broadcasting.

Potential Audience Maps Based Upon the Fan Mail Received By a Station. Historically, this was the earliest method used by radio stations to estimate their potential audience in terms other than the physics of a station's signal strength. Sometimes mail is solicited by means of a premium or gift token. Maps are then made in terms of the number of letters received per one thousand radio homes in a city or county. Maps expressing the *density* of listeners per county can be made on the basis of different proportions of returns. This method has, however, been thoroughly discredited because of the uncontrolled character of the sampling. The fan mail method, which has also been used to estimate the audiences of programs as well as of stations has been superseded by the systematic mail and interview procedures described in the following sections. The importance of fan mail for other purposes, however, especially in the analysis of the public's reaction to broadcasting, is not to be underestimated. The volume of mail itself, is amazing. In 1941, the National Broadcasting Company and its affiliated stations received more than 6,750,000 letters.

B. AUDIENCE COVERAGE AND CIRCULATION

Maps of Audience Circulation Based Upon a Mail Ballot From Radio Homes. This method has been most intensively developed by the Columbia Broadcasting System. It will be the basis, with some modifications in procedure

but not in principle, for the audience surveys of the Broadcast Measurement Bureau set up in 1943 as an industry research organization, under the auspices of the Association of National Advertisers, the American Association of Advertising Agencies and the National Association of Broadcasters.

The method of the mail ballot attempts to measure the scope of a station's audience for the weekly cycle of broadcasting, on the basis of the *listening habits* of a controlled sample of respondents, as determined from their replies to a mail questionnaire. A station's listening area may be differentiated into several types, as for example, primary, secondary and tertiary, with the differences depending upon the number of listeners to the station—to yield *intensity* of audience circulation. For example, the Broadcast Measurement Bureau is planning for its first nationwide survey, to be conducted in the spring of 1946, to define the primary area of a station in terms of all those counties in which the station is listened to one or more times a week by at least half of all radio families replying to the questionnaire; the secondary area, all additional counties in which the station is listened to once or more a week by from one-quarter to one-half of the radio families replying; and finally, the tertiary areas, those counties in which the station is listened to once or more a week by between 10 per cent and 25 per cent of all radio families replying. Reports on each station's audiences, set up by states and counties will then be made, from which maps can be constructed on the basis of the preceding criteria to give a picture of the audience circulation of a station.

It will be observed that this method bases the measure of audience potential on some degree of actual listening; consequently, the results obtained are more often described today as yielding an index of audience *circulation*. However, in the projection of survey results on to maps and into the future, the index is one of a station's audience potential based on some regularity of listening.

The ordinary sampling defects of mail questionnaires can be obviated to a considerable extent in this mail ballot method by an intensive follow-up of respondents. In the case of the most recent survey by CBS (released in 1945), a 75 per cent return on 250,000 mail ballots was thus obtained. According to present plans, BMB

may attempt to secure a large return, from one million ballots to be mailed, by offering an inexpensive gift token to each respondent. Whether, however, such a procedure will be effective for A and B (high income) homes is questionable. It remains to be seen whether a controlled sample of one million radio homes in the United States will yield a return that can adequately portray the daytime and evening audience circulation for all stations in the 3,072 different counties of the 48 States.

Station Popularity Maps. An interesting variation in the mail ballot method is illustrated by the station popularity surveys of the National Broadcasting Company. In the most recent nationwide survey made by NBC in 1944, more than three million post-card "ballots" were mailed to radio homes in all counties and cities of the United States. Included in NBC's survey was the question, what station do you listen to most?, as well as the question, what stations do you and your family listen to regularly? Less than 10 per cent of the cards were returned, to give an uncontrolled sample of less than 1 per cent of the radio homes in the United States. Aside from the question of adequate sampling, NBC's question of "listen to most" has provoked considerable controversy. It is contended that the results to this type of question are a better index of station (or program) popularity than of audience circulation.

Maps of a Station's or Network's Audience Circulation Based Upon Personal Interviews in Radio Homes. This method for the determination of the audience circulation of a station has been extensively developed by Dr. Summers (now of the American Broadcasting Company) and Dr. Whan of the University of Wichita. In 1944, the radio homes of the states of Oklahoma, Kansas and Iowa were sampled by Dr. Whan and his associates. These surveys represented a continuing study for both Iowa and Kansas and an initial one for the state of Oklahoma.

The Iowa 1944 study was the seventh consecutive annual survey of radio listening habits and preferences of Iowa listeners. However, because of the gasoline shortage, the farm homes were not sampled by personal interviews, as in previous years. The rural results were obtained from questionnaires sent to parents in farm homes via children in rural schools located in each of the state's 99 counties. All of the village

and urban results, however, were obtained by personal interviews, as heretofore. A total of 8,513 home replies were obtained—an average of one home for each 67 radio homes in the state.

Each respondent was asked to name four stations listened to regularly during the daytime, and after 6 P.M. The question of station popularity was also asked: "To which one of these four stations does the family listen most?" Both types of replies were used by Dr. Whan to develop audience maps of Iowa stations (a Chicago station, WGN, has ranked third since 1940 for the evening period, in per cent of replies for "heard regularly"). As we have already indicated, "heard regularly" is a fairer basis than "listened to most" for audience circulation maps. Dr. Whan uses five types of areas of per cent of regular listeners by counties: (1) 80 per cent or more, (2) 60 per cent to 80 per cent, (3) 40 per cent to 60 per cent, (4) 20 per cent to 40 per cent, and (5) less than 20 per cent. One station, WHO of Des Moines, has had a high primary audience (80 per cent or more of regular listeners) for a great majority of the state's 99 counties since the inception of these surveys.

Provided that trustworthy and properly trained interviewers are used, the home interview method has several advantages over the mail ballot method in that the sample can be more readily controlled, and longer questionnaires can be used to obtain a great deal more information about the listener. For example, in the WHAN surveys questions are regularly included that serve to give detailed information about the listening habits and program preferences of respondents, which can in turn be analyzed in relation to listener differences in sex, age, residence location, education, occupation, telephone homes, automobile homes and daily newspaper subscribers.

Combined Mail-Ballot and Personal Interview Method. One of the most intensive surveys yet to be attempted has just been announced for the summer of 1945. The survey is to be conducted under the auspices of the Federal Communications Commission and is aimed at obtaining information on the amount and kind of radio listening in the United States, especially in rural areas. Several hundreds of thousands of mail questionnaires are to be supplemented by personal interviews of radio families in rep-

representative counties of the United States. This combination of the methods of the mail ballot and home interview should yield a much more satisfactory result than can be obtained by the mail ballot alone. The carefully controlled sample of interview results can serve as a basis for checking possible errors in the mail returns for those areas in which both methods are used, provided of course that the interviews are conscientiously and expertly made.

D. RADIO'S LISTENING AUDIENCE

In contrast to the audience research methods described in the preceding paragraphs, there are additional quantitative procedures in use set up to determine both the size of the listening audience, and, specifically, to what it listens. They are not only ear-counting techniques; they are also methods for grossly differentiating the station *choices* of the listening audience. In fact, the methods now to be described yield information that has come to be accepted by many radio advertisers as the yardstick of the success or non-success of their programs.

Listening-Audience Ratings for Programs and for Stations By the Method of Coincidental Telephone Interviews. The method of the coincidental telephone survey was originally developed on a national scale by the C. E. Hooper organization in 1938. In more recent years it has also been adopted by the Cooperative Analysis of Broadcasting, (CAB), an organization set up in 1931 by advertisers themselves to measure the listening audience.

The semi-monthly sample of radio homes used in the Hooper surveys is drawn from telephone homes in 32 cities, chosen for their large size and urban areas in which each of the four networks have local outlets. The method is "coincidental" in that telephone calls are made to random samples of radio homes to determine what programs are being heard at the time the call is made.

The coincidental telephone surveys of radio listening yield several types of quantitative audience data, per program, per time period, or per station, as follows:

(1) *Available Audience Ratings.* This is a percentage that indicates the proportion of telephone calls made answered by radio homes to the total number of telephone calls attempted. It therefore gives an estimate of the proportion

of people at home with radios who could be listening and who therefore constitute a potential available audience.

(2) *Sets-in-use Ratings.* The sets-in-use rating is also a percentage. It gives the percentage of radio homes in the sample that had a radio turned on. These ratings for each fifteen minute period vary considerably from day time to night time and from winter season to summer season. The peak for the winter season of 1944-45 was reached in February with an average rating of 34.1 for the evening period, and an average of 16.8 for the daytime period.

(3) *Program Ratings.* A program rating is a percentage taken to the same base as the availability and sets-in-use ratings. It is an index that gives a measure of the percent of radio homes in the sample that had their radios tuned to a particular program being broadcast at the time of the interview. Program ratings vary tremendously. During the winter months the Bob Hope and Fibber McGee shows have had ratings higher than 30.0; however, the average for sponsored programs is about 10.0. During the summer months, on the other hand, an evening program rating of 10.0 is very high and the average drops to between 5.0 and 6.0. For the daytime period, program ratings are generally lower, with an average for sponsored programs ranging between 6.0 and 4.0 during winter and summer months.

(4) *Share of Audience Rating.* This index gives an estimate of the per cent of listeners who are listening to a particular program during a 15-minute period. These ratings thus indicate the program's share of the listening audience. They vary even more than program ratings, but cannot be intelligently considered independently of the latter.

(5) *Sponsor Identification Rating.* A sponsor identification rating of 100 per cent would mean that all of the sample of listeners to a given commercial program could identify the sponsor or product advertised. Such an index presumably affords an indirect measure of the effectiveness of commercial announcements on a program. And it certainly can be maintained that unless the sponsor or product advertised by a program is known to the listener, the program has little or no chance of influencing his buying habits. Sponsor identification ratings also vary greatly for different programs. For

obvious reasons, the Lux Radio Theater has long maintained one of the highest S.I.R.'s,—more than 90 per cent.

(6) *Audience Trend Ratings.* Both the Hooper and CAB coincidental telephone surveys are made on a continuing basis and consequently the trends for the preceding types of ratings can be chartered as time series. Striking is the similarity of available audiences and sets-in-use trends during the past several years. Audiences begin to fall off with the approach of the spring and summer months, and begin to rise at the end of the summer season. However, it is again to be emphasized that availability ratings do not fluctuate seasonally as much as do the sets-in-use and program ratings. The policy that many sponsors have of dropping their popular big-name programs during the summer months is undoubtedly an important factor in this picture. However, the negative effect of other home activities on radio listening during the summer months is no doubt also great.

The chief advantages of the coincidental telephone method for surveying radio's listening audience lie in the fact that a truly random sample of the "universe" of telephone homes can be obtained; errors arising from faulty memory are at a minimum, or entirely eliminated; and a survey can be quickly made. On the other hand, the chief disadvantage of the method arises out of the fact that only telephone homes can be included in the survey. Only about half of the nation's homes are equipped with telephones. The sample result may not, therefore, be representative of the listening of all radio homes. Whether or not this is the case can, however, be checked periodically by other survey methods that will yield data for both telephone and non-telephone homes.

Listening-Audience Ratings By the Method of Telephone Recall Surveys. For many years the telephone surveys of listening made by CAB were based upon a recall, rather than on the coincidental method. That is to say, a sample of listeners was telephoned during the morning and asked to name the programs heard the night before; similarly the afternoon sample was questioned about its listening during the morning immediately preceding, and the early evening sample was questioned about its listen-

ing during the afternoon. This method was finally abandoned by CAB in favor of the coincidental telephone survey because the unaided recall method tends to operate in favor of well-known programs and to the disadvantage of relatively unknown programs. Both memory errors of omission and commission are common.

Listening Audience Ratings By the Roster Method of Aided Recall in Home Interviews. The roster method of aided recall has been extensively developed for the New York and Philadelphia areas by Pulse, Inc. Pulse's samples are taken by home interviews each month and are stratified with respect to economic type of neighborhood. Within each stratum of A, B, C and D homes, the attempt is made to obtain a random sample of radio homes. After each respondent has recalled the time when his radio was on during the morning, or afternoon, or evening, a roster of the programs broadcast over the stations of the city is presented and the respondent is asked to check those programs heard. Although the roster, personal interview method can be used on a coincidental basis, it has been found to be more feasible when employed on a recall basis. This is particularly the case from the point of view of cost and sampling, since a whole morning period of broadcasting can be quickly covered in an interview at noon.

The roster method in home interviews yields sets-in-use ratings, program ratings, audience trend ratings, etc., similar in type to those already described for the coincidental telephone surveys. In addition, this method has the potentialities for the determination of the characteristics and radio behavior of people, already seen to be an advantage for home interviewing.

The chief disadvantages of the roster type house-to-house survey are two-fold. One is inherent in the character of the method and the other is a technical, sampling problem. We have seen that whenever a method of recall is used prestige programs are more likely to be erroneously checked as heard, and little known programs are more likely to be overlooked. However, the roster method does not suffer so much in this regard as does unaided recall inasmuch as the listener's memory is reinforced. He has a chance to see the names of little known programs. The technical disadvantage is that which

besets the attempt of an investigator to obtain random or stratified random samples of interviews. It is fairly easy to draw a random sample of 3,000 telephone homes from a population of several million such homes. It is much more difficult to obtain a random or stratified-random sample of home dwelling units by door-to-door calls in a city or other geographical area.

Listening-Audience Ratings By Automatic Recorders Attached to Radios. The A. C. Nielsen Co. of Chicago experimented with this method over a period of seven years, at a cost of more than one million dollars, before making its Radio Index service regularly available, beginning in December 1941. A mechanical device attached to a home radio, by consent and with the cooperation of the family, automatically records on a tape the exact time the radio is on and off, as well as the station to which it is tuned.

About one thousand audimeters are now in operation in a cross-section of homes—both rural and urban, telephone and non-telephone—extending from the Mississippi River to the Atlantic Coast. As additional instruments become available, this sample is being extended to cover the nation. The data on listening and listening behavior obtainable by the method are extensive in both their quantitative and qualitative implications for audience research. For the population sampled, they furnish the basis not only for an estimate of how many homes are listening (tuned in!) to a program at any time, covering all hours of the day and night, but also information about the variations in the size of audience at each point throughout a program, the average duration of listening per "turn-on" of radio, the turnover of audiences for a program from day to day or week to week, the flow and switch over of the audience from one program to another, analysis of listening by income groups and other factors known about the sample, etc.

The audimeter method of measuring listening can also be combined with other techniques, especially the home interview, mail questionnaire, pantry inventories, etc., to yield relevant inter correlations of radio behavior with other kinds of behavior, as for example, the buying and consumption of advertised brands of commodities.

The main criticism that has been levelled at this method has been to the point that the audimeter doesn't measure *listening*, when a radio in a home is on and no one hears it.

The Listener Diary Method for the Study of Listening Audiences. The listener diary method yields pertinent data on how many people listen, when they listen and to what they listen, as well as information of a more qualitative kind. When the diary method is used to study the reactions of listeners to specific programs, the method is then usually described as the listener panel technique. The procedure of the listener diary method consists in setting up a sample of radio families in the area to be surveyed. Each family is asked to keep a diary of each quarter hour of listening over a period of broadcasting, usually a week.

An advantage of this method lies in the fact that the sample can be carefully controlled so as to be relevant in chosen respects, such as socio-economic status of the population being studied. No attempt has been made by this method, however, to develop periodic program ratings similar to those obtained by the methods cited in the preceding sections. Obviously the reliability of the method depends upon the conscientious cooperation of the homes included in the sample. This is in itself a selective factor, which possibly may make the results obtained atypical for the population sampled. The chief usefulness of the diary technique lies in its use as a panel method for the qualitative study of audiences and will be referred to later in this connection.

E. QUALITATIVE STUDY OF AUDIENCES AND OF PROGRAM PRODUCTION

In the preceding section we have reviewed the chief methods of research used in the field of radio for the purpose of determining how many people listen, when they listen and to what they listen. We see that these methods are basically ear-counting techniques and yield the quantitative data about potential audiences, of coverage and circulation, as well as about actual listening. We are now concerned with qualitative research methods; that is to say, we shall describe the chief techniques in use to determine who the listeners are, what they are like, how they listen and why they listen.

Most of this research to date has been oriented

towards the determination of an analysis of some of the characteristics of the radio audience and of their program preferences. Studies have also been made of the audience characteristics of stations as well as of programs to determine the dialing behavior of listeners with respect to the regularity of their listening to a given program or station and the extent to which they tune to programs rather than to stations. The attitudes of audiences to given programs have also been analyzed for the purpose of program building—for the determination of what it is that people like or dislike about a program, why they wish to listen or don't wish to listen. The chief method developed for qualitative studies of the latter kind is that of the program analyzer and audience reactograph techniques.

WHO ARE THE LISTENERS?

This question of who are the listeners, what they are like, is generally a problem of determining the composition of the radio audience. The attempt is made to determine the basic characteristics of listeners with respect to such factors as sex, age, education, occupation, socio-economic status, etc. Since, as we have seen, radios are available to practically everybody for listening, this problem has today come to be localized as that of determining the composition of the audiences for a particular program or for a particular station. The problem has, however, its negative side, namely, the determination of the characteristics and attitudes of people available for listening, but who do little or none of it.

One of the methods commonly used to determine who are the listeners is that of the personal, home interview, aided by carefully prepared interviewing techniques and tested questionnaires. Relevant information on these questions, particularly for national network programs, can also be obtained for telephone homes by telephone interviews, even though the population studied by this method is restricted by virtue of the fact that less than one-half of the homes in the nation have telephones. Data on audience composition can also be obtained by the distribution of questionnaires by methods other than the personal interview, as, for example, the mail ballot or by Dr. Whan's 1944 method of sending questionnaires into homes via high school students. The chief short-

coming of these latter methods lies in the danger of bias through inadequate samples of listeners, as well as of homes. Unless, for example, a very high return is received from a carefully planned mail ballot of a random, or stratified-random, sample of a population, the returns are likely to be biased and, unfortunately, biased in ways not entirely ascertainable.

The Nielsen audimeter method is useful in giving a picture of the economic type of home composing a program's audience. The audimeters, of course, don't record who in the home was listening. However, by mail questionnaires and personal interview procedures, the objective record of the "dialing behavior" of the radio can be supplemented to give a more detailed picture of what the listeners to a program or station are like. The economic factor alone is, of course, of great importance to the advertisers. Thus, Nielsen reports for an average of thirteen programs of concert music that 13.9 per cent of upper income homes were tuned in, 11.6 per cent of middle income, and 9.2 per cent of lower income homes. By contrast, for an average of ten daytime serial programs, 7.7 per cent of upper income homes, 8.6 per cent of middle income homes, and 10.3 per cent of lower income homes were tuned in. Many programs are found to have higher ratings in rural homes than in urban homes, and vice versa. Sex, age and education are also three important variable factors in the composition of the audiences of different programs or time periods and different stations. Dr. Whan, in his study of the 1944 Kansas audience finds, for example, that a greater proportion of urban men than of women listen from 10:30 to 11:00 at night; that the chief age difference in listening occurs in the late evening hours, with, as might be expected, a greater proportion of young people than of older people doing the listening. Because of the correlation of education and age, more of the college people also listen during the later evening hours.

The importance to the advertisers of such information about the composition of a program's audience is obvious. If he sells a product, such as tooth-paste, that is widely purchased by people of both sexes, by adults of all ages, by people regardless of their education, income status and type of residence, he naturally wants a type of program that has an appeal for all

kinds of peoples. On the other hand, a cigar manufacturer is more concerned in having a hearing by a male audience, and is less concerned about women listeners and young people.

HOW THEY LISTEN

The question of how people listen is differentiable into two major aspects. On the one hand, it is relevant to ascertain what people do while they are listening, and, on the other hand, it is obviously of value to determine how they select their programs. Both of these types of problems have been studied by methods utilizing personal interviews, mail questionnaires, and the second type of problem dealing with the dialing behavior of listeners has also been most objectively studied by the use of audimeters attached to radios in their homes.

Co-Listening Activities. A pioneer study on the problem of determining what people do while they are listening was conducted more than a decade ago by Frank Stanton, who used a mail questionnaire sent to homes of a sample whose radio behavior he had studied by the use of mechanical recorders attached to their radios. He asked the listeners to check the following: "The radio was turned on while I, write, dance, bathe, sew, eat, study, lie in bed, clean the house, read, play, iron, work, rest, talk, ride, cook, boat—and listen (that is, do nothing else)." Space was provided for the listing of additional activities and the listeners were directed to check only those things that they did regularly. For men, the highest co-listening activities were eating, resting and reading. For women, however, the story was different. Their co-listening activities were chiefly sewing, resting, ironing, eating, cleaning, reading and cooking. Such sex differences are obviously attributable to the home occupations of women and their greater availability for listening during the day.

Another early investigation was conducted by A. L. Eisenberg about ten years ago in a study of the role of radio in the lives of several thousand metropolitan New York children: 38 per cent of the girls and 28 per cent of the boys reported co-listening activities. The chief co-listening activities of the boys and girls were reading, doing homework, eating, and playing, with sewing also an important co-listening activity of the girls. Radio has become today one of the principal leisure time activities of chil-

dren. In fact, for people generally, listening to the radio probably occupies more of their time around the clock than any other activities excepting sleeping and working.

It is well known that some types of program material is much more suited for co-listening activities than are others. During the war some research progress has been made in the programming of music while people work. Obviously music that is in the tempo of a funeral dirge or of hot jazz is not conducive to the maintenance of good working habits. On the other hand, music of types found to be appropriate has been found to be the most appropriate radio material for listening during different kinds of work activities whether in the factory or in the home. The extent to which the daytime serials represent the most satisfactory radio material to the housewife while working has not been satisfactorily determined. However, the high program ratings obtained during the morning period by music and audience-participation shows, such as *The Breakfast Club* and *Breakfast at Sardi's* of the American Broadcasting Company and straight programs of popular music such as Martin Block's "Make Believe Ballroom" over WNEW in New York, definitely indicates that many housewives do not prefer serial dramas while they work.

Adjacent Listening—The Flow of Audiences. The tuning-in, tuning-out, and switching-over behavior of listeners in the dialing of their radios offers a very fruitful field of research in the qualitative study of listening. The two chief sources of information available today on this aspect of audience behavior are through the roster method of aided recall in home to home interviews, as developed by Dr. Roslow of *Pulse* in New York and Philadelphia, and the audimeter surveys of Nielsen. In the roster method, the respondents are asked to check the programs that they heard over a period of time. In the latter case, the audimeter objectively records not only when the radio is on and off, but also the station or program to which the radio is tuned at any particular moment. The habits of listening homes from program to program, and during a program, can thus be readily ascertained. A listener or listening home can be characterized in terms of what was listened to before and after a given program. In other words, in addition to the tuning in and tuning out behavior of the listener, pertinent informa-

tion about adjacent listening both before and after a program, as well as the flow of the audience during the program, can be ascertained. Thus, for any given program, the following information is relevant and available:

1. The proportion of a program's audience that did not have their radios on, either before or after the program.

2. The proportion of the audience that also was tuned to a program on the same station, either before or after the particular program.

3. The proportion of the audience dialed to programs on other stations, either before or after their listening to the particular program.

Information of the first type provides a basis for estimating the specific appeal for the particular program. Thus, if a program has a great proportion of tune-ins and tune-outs, it is evident that the listeners turned to their radios because of the particular appeal of that broadcast. Information of the second and third type provides a basis for an estimate of station "loyalty" and switch-over behavior of listeners. When such data are analyzed for the possible interrelations of program appeals and the characteristics of listeners, pertinent information of value to the producer and advertiser alike is obtained.

The audimeter also provides a record of *program loyalty*. Nielsen reported in 1944, for example, a "holding power" of 85 per cent (per cent of total programs tuned to by average home) for daytime serials, 79 per cent for news programs, as compared with 63 per cent for popular music and 59 per cent for concert music.

An example of adjacent listening is provided by Fishman and Roslow in *Radio Research: 1942-1943*. In an analysis of listening to "Your Hit Parade," broadcast over the Columbia Broadcasting System on Saturday evenings, 41 per cent of the sample of listeners in New York to WABC (CBS's station) were found to be tune-ins, and 29 per cent were tune-outs. An additional 21 per cent were already tuned to WABC at the beginning of the program, and 60 per cent continued listening to the broadcast over the same station at the conclusion of the program. The switch-over from one station to another was much greater at the beginning than at the end of the program: 38 per cent of the listeners to the Lucky Strike broadcast had switched their dial from another

station at the end of the broadcast. It is evident that this program had a very specific tune-in appeal for a large part of its audience and that the program following also profited.

The results of adjacent listening studies have revealed a greater degree of specific appeal for news programs at certain times of the day or evening than for any other type of broadcast. For example, the same authors in an analysis of adjacent listening of a Frank Singiser news broadcast over WOR, of the Mutual Broadcasting System, New York, at 6:30 P.M., two-thirds of the audience were tune-ins and about one-third of the audience were tune-outs. Interestingly enough, another one-third switched over to Lowell Thomas's news program on WEF of the National Broadcasting Company at 6:45 P.M.

The Cumulative Audience and Audience Turnover. A further type of audience behavior that has received increased attention in recent years is that of the turnover of audiences. Although this problem considerably overlaps the domain of quantitative methods for estimating the audience circulation of a radio program, it nevertheless is germane to the qualitative study of listening behavior, particularly when the latter is analyzed with respect to such factors as sex, age, education, etc. The point is that many more people listen to a program at least once a week, or once a month, than listen to one particular broadcast.

One study by the listener diary technique indicated that a daytime serial drama had total listeners during the week that numbered but 80 per cent more than the listeners on an average day, whereas a musical program had listeners 190 per cent greater during the week than for an average day. The national survey made by Elmo Roper for the Columbia Broadcasting System, earlier referred to, revealed that many programs have a monthly audience two or three or four times larger than that of a single broadcast. Nielsen has given considerable attention to this aspect of audience research. The audimeter records of his 1944 sample of a thousand homes reveal a considerably higher turnover for daytime shows than suggested by the preceding diary study. Thus the average daytime program was tuned to by 8 per cent of the sample homes for one broadcast, but by 30 per cent over a period of four weeks. This signifies a considerably greater impact value

for the advertiser using daytime programs than their low audience ratings per broadcast would suggest.

WHY THEY LISTEN

A systematic and a detailed answer to the question of why people listen gets at the heart of the psychology of radio listening. The general question, however, needs to be subdivided: Why do people listen at all, and why do they listen to the particular programs chosen from among the many available? The answer to the first one of these two questions is known in a general way. People listen for relaxation or entertainment; they listen for information; they "listen" with no particular object in mind, having nothing else to do. However, the relative importance of each of these types of reasons for listening, analyzed further with respect to sex, age, education, occupation, etc., of listeners, constitutes the questions for research, and, as we have previously indicated, the question of why they don't listen is just as important from the point of view of broadcasting and program building as the question of why they listen.

The chief methods in use for ascertaining the reasons why people do or do not listen are those of the personal interview and the mail questionnaire. The personal interview method has been employed in home-to-home surveys, with listener panels and with the program analyzer technique. The mail questionnaire, however, is too unreliable a method for a direct attack in this basic question of "why?"

Program Preferences—Likes and Dislikes of Audiences. The program preferences of listeners throw some light on reasons for listening. For example, the Whan surveys of the Iowa listening audience for five successive years, 1940-1944, reveal that news broadcasts have rated highest as the best-liked program type, with about 75 per cent of women and more than 80 per cent of men checking this kind of broadcast as among their five best-liked types. Comedy programs have consistently ranked second, with more than two-thirds of both men and women liking this type of program, and popular music has generally ranked third, being liked by nearly 50 per cent of the respondents.

It would therefore appear that one of the most important reasons for radio listening for both men and women is to obtain news information. This has been accentuated by the war.

The next most important reason is for entertainment and relaxation. Many people also appear to listen for inspiration; about one-quarter of Iowa women and about one-sixth of Iowa men checked religious music as a type of program liked. Other types of information, in addition to news, were also liked; about 10 per cent of both men and women in Iowa checked talks on farming as a best-liked type of program material.

An analysis of preferences for specific programs, rather than of program types, throws additional light upon "why they listen." According to the 1944 Whan survey of the Iowa audiences, 46 per cent of men and 41 per cent of women checked the Fibber McGee program as one of their best-liked programs—and indicated that they "liked the program well enough to try to hear it regularly." The Bob Hope show came second with both men and women, but with men the WHO (Des Moines) news broadcast ranked third and with women the Lux Radio Theater ranked third. With women, the WHO news broadcast ranked fourth. Beyond this point the difference in the preferences for specific programs of men and women were rather striking. However, in view of the general availability of news broadcasts at various times of the day, the interesting point about these results is that a specific news program ranked so high. This again points to the quest for up-to-the-minute information about the news as one of the fundamental reasons for listening. When Iowa listeners were asked, "On which do you depend most for national and war news? . . . newspapers, radio, magazines, or conversation with other people?", more than two-thirds answered radio. This figure is particularly significant in view of the fact that 94 per cent of all families interviewed stated that they subscribed to a daily newspaper. As would be expected, the proportion depending most on radio was considerably higher for farm men and women (being nearly 80 per cent) than village and urban folk.

A classification into program types of all those specific programs checked by the Iowa listeners as their best-liked ones, revealed that comedy programs were first with both men and women, and war programs were last with both men and women. Only about 1 per cent of men and women named the latter type of program among their best-liked ones. Dramatization of

example, musical bridges, or terse announcements, or gags, are overdone or not well-done can be ascertained.

The study of listener attitudes and the determination of the reasons for their attitudes is essential to any sound approach to the problem of program building. There is little excuse today for a producer of a program to rush on to the air with an unrehearsed broadcast and with all fingers crossed, wondering whether the audience will like it. By the use of the Program Analyzer or the Audience Reactograph technique, radio programs can be pre-tested. Many of the "bugs" can be eliminated and the producer can go on the air with a program in which he can have justified confidence. The chief difficulty in the use of these techniques lies not in the method itself—which has been demonstrated to be satisfactory—but in the problem of sampling. Adequate cross-sections of the audience need to be employed in order for an analysis to have sufficient validity to be acted upon in the revision or recasting or general evaluation of a broadcast.

The Listener Panel Method. The listener panel method consists of the selection of an appropriate sample of persons who agree to listen to a series of broadcasts and report their reactions to what was heard. Formal questionnaires are usually provided for this purpose. As indicated earlier in the listener diary method, this technique has the advantage that arises in controlled sampling. Elaborate questionnaires can be used to obtain a great deal of relevant information about the listeners themselves, as well as about their listening habits, program preferences and reactions to the programs heard. Furthermore, the method of the listener panel has the advantage that the listening is done and the questionnaire is filled out in the home situation. Bias, of course, may enter into the result. Panel members may have favorable attitudes because of a desire to please or they may develop unduly critical attitudes, or they may tend to express what they think they should say rather than what they think. In other words, the method itself, being essentially a questionnaire technique dependent on the conscientiousness of the respondent, is subject to unreliability of measurement, even though the sample panel can be satisfactorily established.

Mr. C. H. Smith of the Columbia Broadcasting System has employed this method in a

series of systematic studies. Qualitative information of the following kind are reported:

1. An over-all evaluation of a program by means of a rating scale.

2. A measure of the listeners' tolerance for a program—"If you had tuned to this program by accident, at the beginning, do you feel that you would have listened to all of it?" If the answer is "No," the listener then indicates the particular point in the program at which his interest waned (however, it will be observed that the answers to this latter question were not satisfactory inasmuch as some listeners found it difficult to be specific; this points to the advantage of the Program Analyzer method over the listener panel technique for the study of listener reactions and attitudes towards the detailed content of a radio broadcast).

3. The possible future appeal of the program, obtained by asking listeners whether they would listen "regularly" or "only occasionally" or "not at all" to programs of a similar nature.

4. Attitudes about particular aspects of a broadcast such as the commercials, narration, music, etc., by the use of a rating scale questionnaire.

F. MEASUREMENT OF THE "SELLING EFFECTIVENESS" OF RADIO

Intertwined in the quantitative and qualitative measurement of audiences, but in addition to these types of research, is the problem of measuring the actual selling effectiveness of a program. The phrase "selling effectiveness" should be construed in its broadest sense to include more than the selling of advertised products. It includes, for example, the effectiveness of radio in the sale of war bonds, in the drives for the salvaging of metal and of waste paper, for enlistment of women in the military services, for Red Cross donations, etc. In general, it includes the effectiveness with which whatever is broadcast for a specific purpose is "put across" with the audience. A program is thus effective to the extent that it yields results in line with its objective.

Sales Effectiveness of Commercial Programs and Announcements. Research methods for the measurement of the sales effectiveness of radio are but at the threshold of extended use. The radio sponsor is primarily concerned with the effectiveness of radio in the sale of specific products or in the development and maintenance of

good will (institutional advertising) for his brand or trade name. Radio advertising is generally based on at least one of the following three premises: (1) People listen, then they buy; (2) the more they listen, the more they buy; (3) the more they listen, the more likely they are to continue to buy.

The research problem of determining the influence of radio listening on the purchases and buying habits of listeners is usually complicated by the fact that most manufacturers and retailers employ more than the one type of advertising medium. It is difficult to disentangle the sales effectiveness of radio advertising from that of newspaper, magazine, display and direct-mail advertising. Where an advertiser of a specific product is using radio as his only medium of advertising, the research problem is less complicated. Various methods for measuring sales effectiveness have been developed and the chief ones that have been used will be briefly reviewed in this section.

Robert F. Elder summarized some of the early, unsatisfactory methods in a 1931 publication, "Does Radio Sell Goods?" A more recent summary of procedures by A. M. Crossley in an article on "Radio and Sales" was published in *Variety's Radio Directory of 1940-41*.

Sales Volume Before and After Radio Advertising. The determination of selling effectiveness by this method consists in the computation of the sales volume figures of a product for a period *before* and an equal period *after* radio advertising. Even if other advertising media are not employed during such a study, this method is not sound because of seasonal and cyclical fluctuations in trade, variations in sales policies and personnel, as well as in distribution methods.

Consumer Testimony. Another method consists in asking consumers what kind of advertising has most influenced their buying. This procedure is psychologically unsound because many advertising effects are likely to be unconscious. The consumer may think that he knows, but his testimony is all too likely to be unreliable.

A later variation of this method consists in telephoning people while a program is being broadcast to ascertain (1) whether they are listening to the program, and (2) what brand of the product being advertised they use. Unless rigorous controls are used, this method is

unreliable, because of unintentional errors of commission in the association of the sponsor's trade name with the answer to the brand question. Furthermore, interviews alone, whether face-to-face or by telephone, may yield unreliable results about product use and buying habits of some types of products, especially with respect to the regularity of use and volume of purchases.

Analysis of Fan Mail. The analysis of fan mail, whether unsolicited or in response to "free offers," box-top "coupons," etc., may be productive of valuable insights for the producers of programs and the development of commercial announcements, but it is an unreliable method to measure sales effectiveness of radio advertising. A large volume of responses may be elicited but the advertising may not prove effective in selling merchandise. The character of the program itself may be such as to draw many listeners but few buyers.

Brand Usage in Radio and Non-Radio Homes. This is a method recommended by Elder. More than 100,000 post-card questionnaires asking for brand names of nine commonly used, rapid-turnover products, were mailed to homes in ten cities. Brands of each product were heavily advertised in other media, but some brands for each were radio-advertised and some were not. Thus, a comparison of the use of radio-advertised brand names in radio and non-radio homes should show the effectiveness of the radio advertising. Although this post-card method of measuring *use* is unreliable, Elder reported that radio-advertised brands were used in about 30 per cent more radio than non-radio homes. Furthermore, non-radio advertised brands were reported used about 10 per cent less in radio homes than in non-radio homes.

We thus have here the beginnings of controlled investigations in the measurement of sales effectiveness. Even with a more reliable technique for the determination of brand usage, this particular method, however, is of little or no use today because of the small percentage of non-radio homes.

Brand Usage in Listening and Non-Listening Homes. If radio and non-radio homes cannot be used as the experimental differential between otherwise "matched samples," then why not compare brand usage in homes that listen to programs advertising a given product with

brand usage in homes that don't listen to these programs? If more listeners than non-listeners use the product, it has been argued, then the radio advertising has been effective in making sales. The situation, however, is not quite so simple as this. Thus if the *appeal* of a radio program is similar to the appeal of the product, brand usage will be high with listeners. Again, if the program appeal is rural and product appeal is urban, brand usage will be high in urban homes despite a low volume of listeners. Controls obviously need to be employed if the difference in brand usage of listeners and non-listeners is to be taken as an index of the sales effectiveness of radio advertising.

Matched Samples of Listeners and Non-Listeners. Two general approaches, employing controlled techniques, have been developed. On the one hand, the brand usage of matched samples is compared—one sample having had no opportunity for exposure to the radio advertising and the other, having had exposure. On the other hand, the brand usage of matched samples of known listeners and known non-listeners to the radio advertising is compared. The first of these methods requires the use of two separate but otherwise comparable market areas, one of which is exposed to the radio advertising and the other, not exposed. The second requires an accurate record of listening and non-listening over a period of time such that the brand usage of a group of listeners can be compared with that of non-listeners—each group having been matched in relevant characteristics, such as age, sex, education, purchasing power, family and residence status, etc. Both methods require an objective index of brand usage, either by the method of periodic retail store inventories, or of household inventories, or of systematic records of purchases made by an adaptation of the method of the listener diary technique.

An example of an investigation that illustrates aspects of both of these approaches to the problem is reported by Frank Stanton in the *Journal of Applied Psychology* of 1940. The attempt was made to measure the sales influence of a specific radio program. The experimental design aimed to isolate the sales effectiveness of radio advertising alone for a product that was also advertised in other media. How many units of a product did radio sell that would not have otherwise been sold? In market A, the product was radio-advertised; in market B, the

control sample, the product was not radio-advertised. In both of these urban markets the advertiser's sales factors were "exactly comparable." Both markets were also fairly well matched in size of population and the number of retail outlets of the manufacturer's product.

Three types of measurements were made to determine: (1) over-the-counter retail sales of the brand advertised by dealers in the radio market A and in the non-radio market B; (2) whether families in market A that listened to the program bought the brand more, less, or as much as families that did not listen; (3) whether families that listened "regularly" were more frequent buyers of the brand than families that listened only "occasionally." Measurements in both market areas were made as objectively as possible by the use of field investigators who visited the retail outlets and made periodic checks of their inventories and sales of the product. Home listening and non-listening to the program in market A were initially determined by a coincidental telephone survey of a random sample of more than 4,000 families. Families of both listener and non-listener groups were then interviewed. Their customary listening habits to the program were ascertained by carefully constructed questionnaires and the pantry inventories made.

After a month of such field work, it was found: (1) that the total retail sales of the brand of the product were 88 per cent greater among dealers in the radio market areas than among similar dealers in the non-radio market; (2) the use of the brand was 81 per cent higher than the next most popular brand of the product among families that listened in the radio market, but among non-listeners in the same market the use of the brand was only 7 per cent higher; (3) among regular day-to-day listeners in the radio market, use of the brand was 263 per cent higher than that of the nearest competing brand, whereas among occasional listeners the use was only 59 per cent higher.

Further refinements on the preceding investigation have been made. Increased reliability is obtained by the establishment of matched panels of listening and non-listening homes in the same market area, or in two or more areas. The extent of listening and non-listening to the radio advertising over a substantial period of time can be objectively differentiated by audimeters attached to radios. Non-listeners, occasional lis-

teasers, and regular listeners can then be matched for the factors already mentioned, such as purchasing power, family, educational and residence status, etc., as well as for the exposure of both listener and non-listener groups to non-radio advertising of a product (over a period of time, as well as currently). Include with these controls regular and objective inventories of the purchases of the product and we have the essence of a well-designed market research investigation that should reliably isolate, over a period of time, the effectiveness of radio advertising for the products studied.

There is of course no question that, in general, radio advertising, whether through programs or by "spot" commercial announcements, has been effective in the selling of merchandise. The research problem is one of isolating the sales effectiveness of radio for specific products.

Direct Selling By Radio. Some products have been sold directly to the public via radio advertising. The publishing house of Simon and Schuster, for example, recently radio-advertised its \$1.00 annual Income Tax Manual. They sold 750,000 copies on credit by direct mail to people who replied to their money-back guarantee advertising via spot commercials. During the same season, they also sold 750,000 copies via other outlets, but the year before, without radio advertising the total sale was about 750,000 instead of 1,500,000 copies. This result does not of course demonstrate that the use of radio doubled sales. The changed tax situation no doubt increased the general demand. Many listeners, aware of the availability of the volume on newsstands, may have taken advantage of the credit, money-back guarantee feature of the radio-advertised offer. On the other hand, listeners may also have made newsstand purchases as a result of hearing the "commercials." In any event, this example points to the possibilities of the direct selling of some products over the air—and this will doubtless be augmented for mail order houses once television is well developed.

Radio As the Only Advertising Medium. The "pulling power" and sales effectiveness of radio has of course been continually attested to by the advertising of new brand names, or of department store "specials," etc., for which, in a given market area, radio has been the only formal advertising medium employed. By frequent inventories of retail sales outlets, by

household inventories of listening and non-listening homes, determination of trends in sales effectiveness can be more readily and reliably made than when other advertising media are also employed.

Selling Effectiveness of Non-Commercial Radio. Few well-controlled investigations have been published that demonstrate the effectiveness with which radio has sold bonds, recruited labor, influenced public opinion, etc. Millions of dollars of war bonds have of course been sold via radio, but the extent to which they wouldn't have been purchased otherwise has not been isolated. More revealing, perhaps, of the selling effectiveness of radio has been the response to recruitment announcements. And, of course, radio's power to influence public opinion has been suggested again and again—most sensationally perhaps by Orson Welles' broadcast a number of years ago of the invasion from Mars. In the hands of a Hitler, radio is a power to conquer and destroy. In the hands of free peoples, it can be a power for peace and democracy.

RAT IN ANIMAL PSYCHOLOGY, THE.—*Introduction.* It has been said that if one were to write a physiology confined to one form, and one form only, of animal life, as good a physiology of the dog could be written as of man. If a similar statement were made for psychology, the rat would have to be substituted for the dog. In fact, one textbook has been written (25), covering the major topics in psychology, confined wholly to the rat. Judged by scientific standards, it stands up very well,

compared to similar texts dealing with man. Another text (29) concerned more with a systematic development of fundamental principles of behavior than with an outline of the facts, is based wholly on research with the rat. And a third book (32) of considerable theoretical significance has been inscribed to this animal. Most modern introductory texts in psychology do not hesitate to draw on experimental work performed on the rat, and would be much inferior scientifically if they did not do so, for it is true that a great many of the experiments which shed light on modern principles of psychology have been done on the rat as a subject.

The popularity of the rat for experimental purposes came about for a number of reasons. As Donaldson (8) has said,

"The Albinos are clean, gentle, easily kept and bred, and not expensive to maintain. They are omnivorous, thriving well on table scraps. The span of life is about three years and the breeding begins at about three months. . . . The litters are large and may be had at any season. . . . The rat . . . takes exercise voluntarily and is susceptible to training. It is also highly resistant to the usual wound infecting organisms."

A more recent publication (10) points out in its preface that "the albino rat has come to be the most widely used laboratory animal" and that its widespread use has enabled "laboratory workers to compare their results with those of earlier workers in the field and with contemporary research performed in other laboratories."

To the reasons suggested above may be added that of tradition or custom. The early workers found the rat convenient. Their students were introduced to it while taking advanced work, and spread its use to other laboratories. Students of these students continued the process until today, few if any of the larger institutions for advanced training fail to provide facilities for rat research.

Historical Summary. The nineteenth century saw a tremendous development in animal biology in general. Largely as a result of the work of Darwin and his theory of evolution, a great impetus was given to the development of animal psychology. The object of a great deal of the work was to close the gaps in the phylogenetic scale, both with reference to structure and function. Boring (13) has made the impor-

tant point regarding evolutionary theory that the great gap existed between man and all the lower animals. Thus the early workers in the field felt that they were at the crux of the evolutionary doctrine when they were working in animal psychology to study the evolutionary development of mental processes. Among the notable contributors with this point of view directly in mind were Romanes and Lloyd Morgan. Not all of the early workers, however, emphasized this evolutionary viewpoint. Loeb, for example, who exerted a strong influence toward the establishment of animal psychology, emphasized a mechanistic point of view and presumably felt that complex mental processes could be reduced to their simplest terms by studying simple instances of animal behavior.

At the turn of the century laboratories for the special study of animal psychology were being established in this country. Small's study of rat maze learning, performed at Clark University, was published in 1900, and shortly thereafter the Chicago Laboratory, where Watson and Carr and a large number of their students who were to play an important part in the popularization of the rat for animal work, was set up. Watson continued this influence at Johns Hopkins University, and Donaldson, whose rat colony was started at Chicago, carried on his work at the Wistar Institute, so that, after the first decade of this century, psychological research making use of the rat can be said to have been well established.

Many students who were to be introduced to animal psychology during this time were likely to have the field justified for them in some such manner as this: animal psychology could be studied either as an end in and of itself or as a means toward an end. If it is studied as an end in and of itself it could further be for the purpose of understanding the animal mind or to understand animal behavior better. If they were influenced by Washburn, the emphasis was on understanding better the animal mind, and if by Watson, it was on understanding animal behavior. It could also be studied as a means toward the end of understanding either the human mind or human behavior better, and a student of Carr or Thorndike was more apt to have this point of view stressed.

The arguments for these various points of view could run on interminably and many students came to ignore these justifications for

PLATE I—Some typical views of the albino rat. A shows lordosis in the female, to pelvic digital stimulation. B, copulation. C and D, beginning of parturition, E, F and G show typical postures during the birth of the young. H, eating the placenta. I, nest with mother and young. J, young at 21 days of age. Taken from J. Q. Griffith and E. J. Farris, *The Rat in Laboratory Investigation*, Philadelphia, J. B. Lippincott Co., 1942, by permission of the publisher and the courtesy of Dr. Farris.

having animal psychology. The more recent texts by Warden, Jenkins and Warner (36) and by Maier and Schneirla (21) have the flavor of the early evolutionary doctrine. The Warden texts especially have a pattern similar to modern comparative anatomy, and the title *Comparative Psychology*, which deals with plants and invertebrates as well as the higher animals is aptly descriptive of the actual content of the books. The Maier and Schneirla text has a similar pattern, although the emphasis is not so strongly on the comparative nature of responses as it is on the development of principles as progression up the phylogenetic scale is made. In their preface, likewise, they point out that "many problems which cannot be adequately analyzed in human subjects may be successfully attacked when lower animals are used as subjects," an attitude which is certainly not emphasized in the Warden books.

This suggests the main reason for the existence of animal psychology at the present time. Experimental work can be carried on with the animal that would be impossible to investigate in the human. Examples of such work include the study of cerebral function in learning or instinctive activity, the influence of endocrine glands or hormone injections on motivation or general activity, the maturation and functioning of sensory and motor processes, and selective breeding experiments in the study of heredity. If we were limited to the human subject, our knowledge of the basic mechanisms involved would be dependent on clinical cases produced accidentally or on statistical enumerations, both lacking the experimental control found in animal studies.

It is interesting to note that contemporary work on the rat is concerned almost altogether with psychology as behavior and not as experience. Although Washburn (37) developed with considerable care the basis for inferences concerning the animal mind, that is, the necessary reasoning by analogy to interpret what conscious experience must be like for infra-human species, one seldom encounters such attempts when reading the modern literature. Those animal psychologists who do not subscribe to the radical doctrines of behaviorism and who are led to their experimental studies in the hopes of gaining some insight into mind as conscious experience, seem somehow to omit this part of the interpretation from their reports.

Only when the writer lapses into anthropomorphism, a characteristic which no longer carries quite the stigma it once did, are we likely to find anything approaching a description of the rat's experience, leading one to suspect that the investigator is not much interested in his subject's experience, however much he might want to understand his own better.

METHODS

The Design of Experiments. Animal psychologists believe that they obtain their information by adherence to the general principles of scientific methods; that is, they control conditions, vary an independent variable, observe or measure when possible a dependent variable, and draw comparisons. In the phraseology of Max Myer, science is counting and comparing, and most animal psychologists would accept this as a rough description of the fundamentals of their scientific method. However, Fisher (6) has pointed out that scientific expositions frequently stress varying conditions *only one at a time*. The experimenter is said to isolate his suspected causes into a number of "elementary ingredients" and to hold all but one constant. He then studies the effects of this one by permitting it to vary. According to him, this "ideal doctrine" may apply to elementary physics but is an oversimplification for most scientific practice.

"We are usually ignorant which, out of innumerable possible factors, may prove ultimately to be the most important. . . . We have usually no knowledge that any one factor will exert its effects independently of all others that can be varied, or that its effects are particularly simply related to variations in these other factors. . . . If the investigator . . . confines his attention to any single factor, we may infer either that he is the unfortunate victim of a doctrinaire theory as to how experimentation should proceed, or that the time, material or equipment at his disposal is too limited to allow him to give attention to more than one narrow aspect of his problem." (p. 68 ff.)

Actually the scientific method, as it is ordinarily practiced in the laboratory, is something more sophisticated than the simple doctrine which is usually taught in introductory courses. Indeed, the factors or ingredients referred to by Fisher are not too easily identifiable for animal psychologists. A recent study of

regressive behavior in the rat employed a factorial design. Three methods for establishing habit progression were used (electric shock, delay, and non-reward) and three levels of progression established by means of varying the length of the alternative pathway to reach the goal. Although non-homogeneity of variance gave some difficulty, analysis of variance was employed to separate the influence of "methods" and "levels" and their interaction. In this instance the classification of variables is fairly evident. Another study employed Fisher's method to separate the influence of reinforcements and practice in learning a so-called Thorndikian response. In this case a previous study has failed to distinguish between these influences and the experimental design which would separate them is not self-evident. In both studies, it is questionable if the student who has only a naive conception of the scientific method would comprehend them at all.

The application of statistical methods to animal psychology is of relatively recent origin. When one compares present publications with the reports published in the early part of the century, when averages were given without any estimate of their reliability or perhaps with the addition of a mean deviation or two, but with little inclination to interpret these, the lesson is brought home forcibly. Animal psychologists began becoming statistically sophisticated with the controversy over the reliability of their measuring instruments, largely instigated by Hunter. It was next realized that not only were conventional statistical procedures called for, but that newer developments devised for other fields of science could have important applications to their work. The factor analysis methods of Thurstone and others may frequently be useful and are coming into increasing use in the more recent literature. At present they have not shed too much light on the nature of the variables involved in the studies where they have been applied, but we should look forward with some confidence to the realization of this attainment within the next decade.

Of greater significance, probably, at least to the extent of their use up to the present, are the statistical methods of R. A. Fisher, usually referred to as analysis of variance. Although these methods are only beginning to be used to a marked extent in animal experiments, they are being popularized and disseminated in

easier terms for the benefit of research psychologists and one can expect a continuously greater application of them in the future. They have value not only as a greater refinement of statistical methods, but also in outlining the basic plan for research investigations. It has frequently been pointed out that the use of analysis of variance permits not only a reduction in the number of individuals to obtain an equivalent amount of information regarding the variables or factors under consideration, but also that more information may be obtained more accurately. Thus one can obtain information not only of the primary factors which enter into an experimental setup but also with respect to interactions among these which cannot be obtained from conventional designs of experiment. Another important influence these methods have is in forcing the experimenter to outline with greater care before an experiment begins just what it is he wishes to study and how his experiment should be designed to obtain the pertinent information. It might be pointed out in this connection that while the more elementary treatises of analysis of variance are especially helpful toward getting the investigator who is not too well prepared statistically started on these methods by showing how to design an experiment having two- or even three-way classification of variables and while designs involving more than a three-way classification frequently become relatively more complex and difficult to control, that the process can be carried on to include, four, five, or more ways of such classification. Granting that the interaction effects, especially as regards third and higher orders of interaction are difficult to identify and often experimentally meaningless, these may be lumped into experimental error. Nevertheless, the possibility of removing a fourth or fifth class of variable, e.g., individual differences or practice effects, from its effect on experimental error is frequently valuable in reducing the estimate of this error for experimental comparisons.

The Operational Point of View. Like most psychologists, the animal investigator is plagued with the definition of his concepts. Some relief is afforded by means of what has been called the operational point of view. Its outstanding promoter, Bridgman, derived it largely from his scientific experience in physics, and today its further development has been referred to as

"the science of science." It would presumably furnish a basis, if accepted, for the establishment of the scientific method as practiced in the laboratory. Undoubtedly most of the chief discoveries made in science have been independent of this or any other philosophical background except perhaps in an unconscious way by the investigator. As long as it does not get wordy, for example, to the point where it tries to be operational about itself, it probably contributes to the ease of mind of the investigator working on a specific problem in the laboratory.

In very simple terms, the core of the doctrine amounts to this: the meaning that a concept has in science is derived from the operations that are performed in its measurement. According to Bridgeman (4), this came about from the influence which the theory of relativity had upon physics. The older conceptions of, for example, an ideal space and time were inadequate, and a re-definition was called for. What space and time actually are, in physical theory, is dependent on how they are used, and this in turn depends on how they are measured, the actual operations performed in these measurements. Accordingly, the space of common experience becomes that which yard-sticks measure, but there are likewise interstellar and atomic spaces, measured by light years and Angström units, which employ quite different operations, and therefore have different meanings.

Carrying this notion over to psychology, intelligence becomes that which its tests measure; learning, that which is measured when the psychologist carries on studies which he calls learning; instinct, a concept which evolves from another kind of study; and heredity still another, if the processes turn out to be different from those carried on under instinct, etc. The consideration of such broad concepts as intelligence, instinct, learning, heredity, etc., i.e., to what might be referred to as the chapter headings of psychology, suggests both the possibilities and limitations of the operational point of view. In studying learning, for example, the psychologist performs a heterogeneity of tasks which, as we shall see, has defied the efforts of the theorist to reduce them to a set of common properties. For the present we must be content to say we study many learnings, not learning, and we are uncertain as to how many. Less than two decades ago the meaning of "in-

stinct" was subjected to extensive criticism and dropped from psychology as a chapter heading, but this did not dispose of the phenomena usually considered under this topic. If the other chapter headings had received as rigorous treatment there would have been nothing remaining but "the organism as a whole" to discuss and it is doubtful if it could have been differentiated from the environment.

No scientist is ever thorough in the application of a point of view to his descriptions. In studying rat maze learning, the investigator may apply the operational method very carefully in the definition of his particular learning problem. He ignores it in telling what he means by a maze and a rat. Presumably a set of physical, mechanical operations would apply to the maze, although few psychologists could describe them successfully without reviewing introductory physics and even then run a strong chance of failure, but what about the rat? Stevens (30) amusingly discusses what is meant by "Dobbin is a horse" in considering the problem of generality. If we can make the fundamental operation, a differential response or discrimination, we assume "this is a rat," and the experimentalist would probably lock out of the laboratory anyone wishing to contest the assumption. But when laboratories fail to corroborate one another's findings, a frequent suggestion refers to the possibility that "our stock colony" may be different. With inbreeding for homogeneous stock, "this is a rat" is coming to be an insufficient discrimination for most experimental work. Thus the operational point of view may be clarifying in definite problems, but more insight is required before the general concepts are successfully defined and delineated.

Special Methods. Specific methods peculiar to animal psychology are best described in terms of the apparatus used in their investigation. Almost anyone who has ever read an introductory text in psychology is acquainted with the maze, discrimination box, obstruction box, delayed reaction box and assorted varieties of apparatus for particular problems. Of them all, the maze remains the instrument *par excellence* in rat work, largely because it is so well adapted to this animal. A thorough examination of rat maze studies could lead the man from Mars to suspect that this animal was evolved for this special instrument. Today social and edu-

cational psychologists are beginning to speak of the environment as a maze, i.e., a pattern of choices in life involving blind alleys or frustrations, true pathways and rewards. Perhaps I should mention that a maze is a series of pathways with a beginning (starting box) and end (goal or reward box) and usually several blind alleys between them. In the early work a maze was just that, patterned after the one at Hampton Court in England (see fig. 1). Other

usually regard it as learned and therefore not inherited. Yet we read of careful studies showing learning to be a function of heredity. Under these circumstances we might resort to the operational point of view and ask what is meant by the term heredity.

In order to get an answer we should ask what operations are carried on in the genetics laboratory where heredity is studied. Here, in its simplest terms, we find the geneticist se-

FIGURE 3—View of a multiple Y maze, designed by Warner and Warden, an example of a more recent design of increasing popularity. Photograph courtesy of Geo. H. Wahman Mfg. Co., Baltimore, Md.

designs were not essentially different until the subject of maze reliability came up. Then it was found that certain uniformities were desirable and mazes began to be constructed out of units strung together. Popular units included the T, U and Y (see figs. 2 and 3). However, some of the more enlightening studies have come from less reliable and hence less popular designs. For the details of these methods the reader is referred to the more extensive treatments given in animal psychology texts listed in the references.

HEREDITY, MATURATION AND INSTINCTS

With the remarkable development which took place in genetics in the twentieth century, one might expect that the term heredity would have a well-established meaning. But we find the concept used in opposition to environment and also as opposed to acquired. Yet environment and acquisition are hardly synonymous terms. When we think of behavior as acquired we

lecting individuals (plants or animals) of opposite characteristics (structural or functional), crossing them, and determining the results in the offspring. The experiments may involve complications exceeding the understanding of any but the specialist, but as a beginning, they concern at least as much as has been outlined above. If the animal psychologist wishes to study the inheritance of any trait, be it learning ability, neurotic behavior, wildness, handedness, or what not, he follows this pattern. We note that he begins with a discriminable difference (opposite characteristics) which he proceeds to inbreed or cross to discover the nature of the offspring with reference to the trait. The process may have to be carried on for several generations to get meaningful results, but the pattern is clear. One kind of heredity is defined operationally by the breeding experiment—the crossing of opposite characteristics and the determination of the result in the offspring.

It might be that heredity means more than

this, where Mendelian principles, either on a simple or complex basis, do not seem to apply. In studies of skin patterning in fish, for example, a blending results which is said to be difficult to explain by the operation of complex genic conditions alone. Likewise geneticists have not ruled out the possibility of cytoplasmic heredity. Patterns may be laid down in such an early stage of development that it is difficult to draw a line between heredity and whatever else is left—call it un-heredity, for the moment. It is suggested that the axis between the nucleus of the egg and the point of entrance of the sperm may determine bilateral symmetry, and that the sperm does not enter the egg at any point at random but at a point which is previously determined by a pattern already established in the egg. Is this pattern, since it already exists before the fertilization of the egg, inherited, and, if so, what part do genes and chromosomes have to play here?

When such possibilities are taken into consideration, it would be better to qualify the hereditary we have been defining operationally and refer to it as Mendelian heredity, and indeed, this is frequently done. It is too much to expect that this practice would become universally adopted, however, and we can continue to expect the generic term, heredity, to be used in many ways, some of them loose and fuzzy in their meaning, and one of them, at least, standing for some operations which can be carried out in the laboratory, namely, selective breeding experiments. Whether other meanings of heredity will have to be adopted to produce a situation similar to that in physics regarding space, will be determined by future work.

This does not condone the common practice in psychology of ascribing hereditary nature to other concepts which *seem* to imply it. It is one thing to have evidence that heredity plays a part, quite another to *believe* it does, to assume it merely because this has been a common practice in the past. Instinct is a short, concise term, with a simple modifying form, instinctive. Once in good repute, it was banned from the vocabulary, but is coming back into use again. There is a variety of behavioral phenomena to which the term is as applicable and as well determined as other varieties to which other terms are applied with no greater confidence about their meaning, e.g., maturation, motivation, learning, etc.

Stone (31) has outlined how Darwin avoided a strict definition of instinct and how he recognized that no criterion could be applied universally to separate instinctive phenomena from other varieties of behavior. These criteria include performance without experience or without knowledge of purpose, which amounts today to performance of a well-integrated complex response without the possibility of learning. The introduction of the qualification "complex" raises the question of what is meant operationally by this term. It is usually introduced to separate instinctive activity from unconditioned reflex activity, but this "simple" behavior has complex enough features for the neurologist! In his chapter on instinct in the *Origin of Species*, Darwin does refer to the difficulty of separating instinctive behavior from habits which he presumed could become heritable, pointing out in such cases that the distinction between them was indistinguishable. This certainly implies an hereditary nature of instincts and this view is orthodox today. While this may be acceptable as a *belief*, it is certainly in order to question, in keeping with a consistent definition of Mendelian heredity, what breeding experiments were performed to substantiate it. Unfortunately, no experimental work of this sort has been reported and the term should be divorced from its hereditary connotation in the Mendelian sense.

This criticism applies, in fact, to "simpler" reflex behavior. The distinction is often made between conditioned and unconditioned reflexes that the first is learned or acquired while the second is innate or inherited. Thus, Skinner (29) writes that the terms conditioned and unconditioned "could be replaced by others of arguably equal merit. Thus, for example, we might retain the term 'inborn reflexes' and call the new type 'acquired reflexes'" (p. 61). We can assume by "inborn" he means inherited, and they may be, but what breeding experiment established it? The fact of the matter is that unconditioned reflexes are just so many raw facts. What is meant by the term unconditioned is that no processes were carried out in a laboratory to bring them into being. How they came into being is a problem for someone to study. If all members of a species exhibit them, this is another fact, interesting, no doubt, but not evidence of their inheritance. The species may be pure bred with reference to this

behavior so that the Mendelian experiment may not be possible unless a mutation occurs, but this does not make the assumption of inheritance wholly gratuitous.

In 1921, Child wrote (6):

"Apparently there is no escape from the conclusion that organismic pattern is not inherent in protoplasm but arises in the final analysis from the relation of protoplasm to external factors. . . . Cytological investigation, however, has established beyond question the fact that every cell of the individual body possesses normally the full complement of chromosomes and therefore supposedly the complete nuclear pattern of the fertilized egg. Nevertheless, different cells of the body become different and different kinds of organismic correlation arise between them. . . . Local conditions rather than nuclear pattern must be responsible as activating factors for the origin of these differences between the cells, but many biologists have either not discussed the question or have failed to recognize the fact that if all the cells are originally alike they cannot of themselves become different" (pp. 17-18).

The term maturation is used to refer to the differentiation of parts, and to the growth and development of these parts from a relatively simple to the more complex stage where functioning is possible. These changes are to be conceived as no less lawful than the differentia found in Mendelian heredity. Unfortunately they do not build up into nearly as beautiful a conceptual scheme as those subsumed under the laws of unitary characters, dominance and recessiveness, independent assortment, etc. They have been largely studied by the experimental embryologist and the forms which best illustrate their operation are usually lower than that of the rat in the phylogenetic scale.

Thus, Child's principles of physiological gradients have been worked out on planaria, and similar lower forms, rather than mammals. Similarly, Coghill's principles of differentiation of behavior segments from a larger generalized mass were developed from work on the salamander. Studies of maturation in the rat include those of Gonzales, Carmichael and others and in a general way indicate that there are no major exceptions in this form to the lawful principles more precisely illustrated in lower forms.

The general intention of these introductory

remarks regarding heredity, instincts and maturation has been to emphasize the problematical nature of these concepts. The student of animal behavior is not faced with the problem of classifying samples of his field. He does not, in fact, he cannot, select a sample and state: this is inherited; take another and call it matured behavior; pick a third and classify it as instinctive; go on to a fourth and place it with acquired or learned responses; etc. It would not be especially enlightening if he could but the fact is that with respect to any sample of behavior, he is on what Stone (23) has phrased "the trail of developmental controls." He "must look for effective variables operating in an otherwise standard matrix of dynamic factors" (p. 45). He must, in brief, study each sample as a function of a large number of independent and interdependent variables, some of which are controlled through germ plasma (by means of selective breeding), some through the interaction of parts in embryonic development, some through subtle interstitial factors, some directly through the mechanisms at play in the functions studied, and some through external environmental influences. With this in mind we shall go on to a consideration of studies in the rat which have shed some light on these variables.

Mendelian Heredity. The application of Mendelian principles for purposes of selected breeding has been applied to the behavior of the rat with reference to a few characteristics so that it is possible to make something in the way of a statement which expresses more than a belief concerning the inheritance of the following traits or characteristics: *a.* visual discriminations; *b.* maze learning ability; *c.* activity; *d.* experimentally induced seizures; *e.* temperament; and *f.* handedness.

a. Albinism in the rat, as in every other form that has been studied, is a simple Mendelian recessive characteristic. Inferior visual discriminatory ability has been reported for the albino rat compared to the normal pigmented animal. The albino has difficulty making discriminations between horizontal and vertical lines subtending visual angles less than 86', while the pigmented animal is able to carry discriminations down to approximately 52' of angle. In the first case, the retinal image is approximately 79 microns in width and in the second, 48 microns. Since this difference is directly dependent upon the difference in functional ability of the albino

and pigmented eye, it follows that this visual discriminatory ability is accordingly dependent upon heredity. This point is probably so obvious that it has not been emphasized in the literature.

b. Some years ago Tryon (35) began his well-known selective breeding experiment in which maze bright and maze dull rats were in-

bred for successive generations. The pattern of the multiple T maze used in this study is shown in fig. 2. In 1940 he made his last report on the differences obtained by this process. Beginning with a heterogeneous group in which the extremes for brightness and dullness were selected, he was able by the eighth generation

FIGURE 4—Distribution of error scores in maze learning for successive generations of animals selected for "brightness" and "dullness." Only representative generations from Tryon's study are shown. P represents the parental stock with which the study began; F₁, the first generation from crossing "bright" animals with each other, and "dull" animals with each other; F₄, the fourth generation of such selective breeding; and F₈, the eighth generation. It will be seen that, as the selection continued, the lines became increasingly distinct, until by the eighth generation there is very little overlapping in ability between the "bright" and "dull" lines. Reproduced by permission of the National Society for the Study of Education from its Thirty-ninth Yearbook, Part I, "Intelligence: Its Nature and Nurture." Chicago: Distributed by the University of Chicago Press, 1940.

to produce two distinct strains of animal with very little overlapping in their abilities. That is, the duller offspring from the bright line seldom were inferior to the brightest offspring of the dull line. The results for successive generations, beginning with the parental generation and continuing to the 8th filial generation, are shown in fig. 4. (It will be noted that the scale of abscissa changes twice with increasing errors, and a normal distribution was evidently not obtained to begin with.) It will be seen from the graphs that the separation of the two lines becomes increasingly distinct to the 8th generation. The results suggest multiple genetic factors operating in cumulative fashion. Following Tryon's analysis, we might let ABCD . . . represent genes for brightness and abcd . . . represent genes for dullness, so that a bright line would be AABBCDD . . . and a dull line aabbccdd. . . . Crossing these should give AaBbCcDd . . . in the F_1 crossed generation, and all offspring would be alike in this respect. Thus they should all be at the mean, except for chance and environmental fluctuations. At any rate they should show much less variability than further crossing in the F_2 and later generations. Such crossing, however, produced as great variability in the F_1 generation as in the F_2 generation. Tryon has suggested that the results at present can be best accounted for by assuming that some of the factors are dominant for brightness, some (but fewer) are dominant for dullness, and some operate cumulatively. The Minnesota studies, under the direction of Heron, based on a similar plan of inbreeding, are furnishing corroborative evidence, although they have not been carried as far at present. Such studies furnish the best evidence we have for the influence of heredity on learning ability. They furnish an analogy for what might be expected in humans and far surpass the studies of family lines, about which so little is actually known, and of twins, which are the chief arguments for the influence of heredity on human mental ability at the present time.

The bright and dull lines of rats obtained both by Tryon and by Heron have been tested in other situations as well. In one such test in "hypothesis" situations no difference was found in the ability of the bright and dull animals to form hypotheses, although there may have been a difference in the kind of hypothesis used. The

"maze bright" animals tended to use a spatial hypothesis while the "maze dull" animals tended to use a visual hypothesis. Another test, performed, however, only on the F_2 generation, indicated a somewhat higher metabolic rate in the bright animals. A third test of the F_{17} generation suggested that the bright animals ate somewhat more and at a slightly faster rate than the dull animals.

c. Another study, also carried on in the Minnesota laboratory, tested activity by means of the revolving drum. Early generations of active and inactive strains were selected phenotypically; later generations by the progeny test. The F_{12} generation gave well separated lines of active and inactive rats. A maze test of the F_{17} generation indicated that the active strain was significantly superior to the inactive, as measured by error scores. However, the difference of these strains in maze ability was not as great as the difference of the F_4 generations selected for maze performance itself.

d. The study of audiogenic seizures and neurotic behavior has occupied so much recent attention that this is a subject for a special review in this volume. Mention will merely be made here of studies concerned with heredity of this behavior. In one study, key jingling for two minutes each was used to induce the seizure. Depending on the degree of susceptibility thus found, assorted matings were resorted to and the F_1 generation tested in the same fashion. About 75 per cent of the offspring of "neurotic" rats crossed with each other were "neurotic." About 50 per cent of the offspring of "neurotic" rats crossed with normal animals were "neurotic," while none of the offspring of normal animals crossed with each other gave seizure behavior. These results suggested the inheritance of the behavior as a unitary dominant trait. However, later investigations failed to corroborate these results. On the basis of another test, with breeding carried on to the 6th generation, an increase was found in the percentage of seizures for the line suggested for this behavior and a decrease for the line selected against it. In this study it was suggested that the results might be due to a di-hybrid factor, but not to the unit factor suggested in the first study. A still later report points out that the factor of age needs to be controlled in a study of the heredity of this characteristic. There is an increase in incidence of seizures with in-

creasing age up to approximately 150 days, whereupon few of the animals which had failed to show them up to this age were added to the list of those which could be induced to have a seizure. In this study only the F_1 generation of selective breeding is reported with no definite conclusion to be drawn from the data with respect to its heredity. The age factor does indicate, however, the care which has to be used in studying the influence of heredity in a trait of this sort where the precise tests for measuring the susceptibility of the animal to the seizure are not well standardized. From the results thus far reported, it will probably turn out that the characteristic has an hereditary basis, but it is doubtful if this will be even as simple as a di-hybrid factor.

c. The early report of Yerkes on wildness or savageness in rats indicated an hereditary basis for this trait, and later studies have corroborated the findings. When tame albino laboratory rats are crossed with trapped wild animals to obtain half-breeds and quarter-breeds, which could be compared with the wild animals crossed with each other and with the tame line itself, a blending of this trait is obtained so that by the measures used, the half-breeds are about halfway between the wild and the tame, and the quarter-breeds about halfway between the half-breeds and the tame. Of great significance in this connection is recent work indicating that the gene responsible for black coat color also produces tameness. It is marked in the albino by the failure of the black to show up under these circumstances. This work indicates that other genes, e.g., for piebaldism, pink-eyed yellow, hairless, etc., may make similar contributions to temperament.

By using what is called an open-field situation and measuring emotionality or timidity by means of defecation and urination scores which have a high degree of reliability, selective breeding has been reported for the F_4 generation of inbred animals giving low and high scores. The scores were obtained by means of the number of days in which animals exhibited these traits over 12 trial days. The progeny of the inbred emotional animals showed a continuous increase in incidence of the trait to the point where the animals were expressing it in 8 days out of the 12-day trial period. On the other hand, the non-emotional strain did not clear up much in successive generations. However, they

were already at a low level where they were exhibiting the trait on only one day of the 12-day test. These results add conviction to the belief that the trait certainly has an hereditary basis. In the light of the work identifying the genes for temperament and coat color, mentioned above, it would be interesting to see the results from the open field tests on varieties of pigmented animals.

h. Handedness has been reported for seven generations of inbreeding, crossing right-handed animals with right handed litter mates, and likewise left-handed animals with left-handed litter mates. Since this report, the work has been carried to the tenth generation without any noticeable clearance in the lines. That is, the right-handed line continued to have about as many left-handed offspring as right, and the left-handed line likewise. As compared with a number of the other characteristics mentioned above, we have here what seems to be a relatively simple expression of a trait. Nevertheless, it has an aspect of complexity which may make it more involved than that of brightness and dullness, seizure behavior, or emotionality. Animals are not necessarily consistent in the expression of handedness from one situation to another whereas in the other behavior traits mentioned they might be expected to be. Another attempt was made to inbreed ambidextrous animals, but by the fourth generation the line had bred out so that inbreeding could not be continued. The results of this work have led to a very skeptical view of the easy generalizing that seems to be the rule concerning the inheritance of handedness in humans, as found in the literature. In the rat, the evidence is against its inheritance, and there is no evidence one way or the other in the human, though there is considerable rationalizing about it.

Maturation and Instinctive Functions. The earlier observations on growth and development have been summarized by Donaldson (8) and later observations by Nicholson (10). The regularity of such simple facts as the onset of motility 14 to 15 days after insemination, the constancy of the gestation period (normally 21 to 22 days) and later growth constancies such as eye and ear opening, and, within wider limits of variation, of sex behavior, bespeak of lawful control, but these statements of regulation are for the present largely empirical formulations outlining the facts. Coghill's (7) prin-

ciples of differentiation of smaller behavior segments from a larger more generalized mass, of cephalo-caudal and proximo-distal directions of development seem to apply with some modifications to the rat. Whether the regulatory mechanisms are of the nature of metabolic gradients (Child) operating under remarkably constant environmental conditions, or the operation of genic hereditary principles of sequential unfolding with each stage depending on conditions determined by its predecessor, or an interaction of these, has not been determined. Considering the inaccessibility of pre-natal material and the difficulties of control either of physiological gradients or of genic interactions, perhaps the student is expecting too much in suggesting that the mechanisms regulating growth phenomena should be understood.

In the main, a great deal of effort must be expended and no little ingenuity applied to obtain even modest results. Thus, careful study of fetal development to tactual stimulation found a progressive individuation of responses with increasing fetal development and age, suggesting a maturation through normal growth processes of tactual space localization, rather than a learning process in the early primary patterns of spatial perception. Nevertheless, satisfactory controls could not be instituted to answer whether the behavior in question matures or is learned, or whether in fact there is a distinction between the two with respect to such phenomena.

With reference to post-natal behavior, that aspect which has received the most detailed and precise description and experimental investigation has been sex and reproductive behavior, including, in the female, such related phenomena as parturition, nesting, care of the young, and the like. Munn (25) has summarized the early studies; Stone (1) includes more recent studies; and Beach (2) the nervous mechanisms involved. The behavior appears to be under the control of the hormones, especially of the gonads and pituitary. Learning, on the other hand, plays a very minor, if any, part and for this reason it seems appropriate to designate the behavior as instinctive.

The normal male rat reaches sexual maturity at an average of 65 days of age, but copulatory behavior may occur earlier, especially under optimal conditions of nutrition, etc. After maturity is reached, a few animals may not show

copulatory behavior. Castration of pre-puberal animals prevents the occurrence of the behavior. Castration of older, sexually experienced animals results in a gradual waning of the behavior, although some animals may continue to copulate for some time after the operation. Injection of androgens (e.g., testosterone propionate) in normal prepuberal males hastens the development of the behavior. Similar administrations in the prepuberal castrates will initiate the behavior, and in experienced castrates in which waning has occurred, will reawaken it. Animals reared in isolation beyond puberty will show copulatory behavior, upon opportunity with receptive females, about as well integrated on the first occasion as on later occasions or as compared with experienced animals.

In female rats copulatory behavior is correlated to the estrous cycle and occurs in conjunction with ovulation. Young animals reared in isolation until estrus occurs, show similar, fully integrated behavior without the necessity for practice. Ovariectomy abolishes estrus and the administration of estrogens reinstates it and also the copulatory behavior characteristic of estrus. Administration of the hormone in prepuberal females likewise hastens the development of estrus and of copulatory behavior.

Reversals in sex behavior are known to occur. Thus some males will show the receptive behavior, including lordosis, of the female, and some females will show mounting behavior and pelvic thrusts typical of the male. The latter can be accentuated by the injection of testosterone propionate. The hormone injections also increase aggressive fighting and produce anatomical changes such as hypertrophy of the clitoris. The former is likewise increased from the administration of estrogens. It would appear that both male and female behavior patterns are latent in each sex and are normally under hormonal control.

Recent motion picture analysis at sixty-four frames per second indicates the complexity of copulatory behavior and the temporal relations involved in the activity. Non-ejaculatory copulations extend from one-third to two-thirds of a second and elicit an average of 5.6 pelvic thrusts, while ejaculatory copulations extend from 1 to 4 seconds and average 10.7 thrusts. In the same study, three-hour tests gave satiation in about half the animals studied (35

males) with highly variable profiles of copulatory activity during this period, raising the question of the validity of short test periods—for example, 20 minutes—in studying the strength of the drive. Recovery after satiation proceeded at a rate slower than 24 hours and may extend to 4 or even 6 days.

Stone (1) has stated, "The hormones from the gonads appear to be the *sine qua non* for the organization of sexual behavior" (p.1218). But Munn (25) would add, "However, the mere existence of a physiological stimulus not derived from the environment outside of the animal does not explain the pattern of the sexual response." So far as is known at present, the neural mechanisms controlling sex behavior have not been localized. Even if a hypothalamic center were to be isolated, the cerebral cortex plays an integrating part. Cortical destructions up to 50 per cent of the total area in prepuberal males is ineffective in disrupting later sex behavior, and Stone suggests that more of the cortex could probably be removed without effect. However, Beach has since reported certain qualifying differences from extensive destructions in sexually vigorous animals. If the behavior was not interrupted after cerebral destruction it exhibited essentially the same pattern as in the normal animal. But extensive destructions (up to 75 per cent of the total cortex) seem to reduce the possibility of the expression of copulatory behavior. It is as if the threshold of response had been increased by the ablations. Similar results are obtained from sexually inexperienced animals.

Similar but not exactly parallel results are found in the female. Extensive cortical destructions do not affect female copulatory behavior—at least, such animals can and do bear young. But other aspects of maternal behavior are affected. After removal of 80 per cent of the cortex, animals copulate and bear young. Destructions of 30 to 50 per cent of cortical tissue interfere with nesting and care of the young, and destructions from 65 to 80 per cent result in abolishment of adequate maternal behavior (parturition, nesting, and care of the young).

Lashley (16) has outlined four general possibilities as to how the hormones may influence the patterns of behavior to bring about sexual activity. (a) They may stimulate the growth of specific processes, like chemical organizers. (b) They may increase the general excitability

of the organism. (c) They may operate on specific peripheral organs, which in turn inaugurate the patterns through the afferent supply. (d) They may act directly (interstitially) on central patterns already laid down (through heredity, maturation, or both) to increase their excitability. After citing the evidence for and against each possibility, he is led to favor the last, although admitting that the evidence in favor of it is indirect.

SENSORY AND MOTOR PHENOMENA

In a sense all we ever study is animal behavior, so that everything falls under a general heading of motor phenomena. Such a point of view, however, does not make distinctions which are commonly accepted and seem reasonable. When we study discriminative behavior we are not interested in the animal's locomotion as such, but in the fact that he distinguishes between two different situations. If these differ on the stimulus side, for example, one being light and the other dark, we infer that the animal is making sensory discriminations. He could be reading the experimenter's mind, but since extra-sensory processes have not been established and since the behavior breaks down when the differences are equated for light, we draw the easier and more obvious conclusion.

As Kreezer (10) points out, three types of methods are available for investigating sensory capacities in animals: (1) the stimulus-test method, (2) the discrimination-response method, and (3) the conditioned-response method. In recent years most experiments have employed these methods more for some other purposes than to establish the sensory capacities, as such, of the animals. Reference has already been made to the study of fetal spatial discriminations which used the stimulus-test method. The ulterior purpose here, however, was not to discover if fetal rats possessed tactual sensitivity, but to investigate how its tactual perception becomes spatially organized. Likewise, the conditioned-response methods have been used in the rat not to investigate the animal's ability at sensory discrimination, but largely to see if the concepts growing out of the work on conditioning in other organisms hold for the rat. In fact, much of it can almost be said to be less than that. In 1933, Munn was able to say that the conditioned reflex method had not been used on rats. Since then the main objective in

FIGURE 5—Yerkes Brightness Discrimination Box. L is the light box. The animals are started at S, proceed to the discrimination chamber, D, thence cross grids G or G' through the entrance, A or A', to the food box, F or F'. Redrawn from K. S. Lashley, *Brain Mechanisms and Intelligence*, Chicago, The University of Chicago Press. By permission of the publisher.

conditioning work on the rat has been to show that precise, definite, conditioned *reflexes* can be established in this animal. A conditioning of less specific and precise reflexes, of what has come to be called conditioned *responses*, have been studied with reference to problems of learning, but not for purposes of investigating sensory acuity.

Information regarding the sensory acuity of the rat is thus obtained largely from the discriminatory-response method. The apparatus used is some convenient form of choice box, adapted to the particular conditions to be studied. The earliest and perhaps best known of standardized apparatus is the Yerkes brightness discrimination box (fig. 5). It consists of a starting chamber and discrimination chamber where the stimuli are presented, followed by two paths, one leading to the correct choice (food

is usually the reward) and the other to the incorrect choice (electric shock is frequently given as punishment, although delay in reaching the reward can be used). In work on brightness discrimination, the correct path is determined by a random order which prevents solution by adopting a position habit or any other "hypothesis" than the difference in light intensity. It is this apparatus that was used by Lashley in his early studies of cerebral mechanisms of vision in the rat.

The Yerkes box can also be used to study size discrimination. It is not suitable, however, for studies of figure discrimination, and for a long while it was believed that the rat was quite deficient in this respect. However, in the late 1920's Lashley devised his now well-known jumping technique (fig. 6), which clearly showed that the rat has considerable capacity

for such discriminations. This apparatus requires the animal to jump from a platform through stimulus cards to another platform containing a reward. If the correct (positive) card is selected, it falls in onto the reward

FIGURE 6—Lashley Figure Discrimination Apparatus. The jumping platform is at S, the food platform shown at FP, with discrimination patterns shown at L and R. M prevents the animal from jumping too high, and N is a net to break the fall in case the wrong choice is selected. Redrawn from *J. Genet. Psychol.*, 1930, p. 454, by permission of the publisher.

the time of choice and the punishment, bumping and falling, follows immediately upon the incorrect choice and yet is not as disruptive apparently to the adaptive behavior called for as strong electric shock can be in the Yerkes box. Some difficulty is encountered in getting the animals to jump, especially on difficult discriminations. Tapping the animal on the back or tail, air blasts and electric shock have been given on the jumping platform. While these might result in cues, careful controls indicate that the animals discriminate on the basis of the visual differences presented. The comparative ability of albino and pigmented animals has already been given in the preceding section.

With this apparatus Lashley has studied the details of cerebral control for pattern discrimination. The results indicate a higher degree of control by the cerebral cortex than for brightness discrimination. Animals may learn brightness discriminations as rapidly without the visual cortex as normal animals, whereas destruction of the visual areas abolishes pattern discriminations. In recent years Lashley has been interested in what he terms "conditional reactions" (17). After considerable training, the animal is required to select the correct pattern in terms of the background on which it appears. Thus a white triangle may be positive and a white cross negative on a black background. On a black-and-white-striped background the situation is reversed. The triangle becomes negative and the cross positive. The animal is trained until he reverses his choice automatically, and immediately, depends on the background. Lashley believes this reversal involves a higher degree of integration than that for the discrimination of visual figures. A study of the cerebral mechanisms involved indicates that a visual association area or other integrating region than the primary visual cortex is unnecessary to the successful performance of the act. In the rat, Lashley has been unable to distinguish anything comparable to a visual agnosia or amnesia as found in man after cerebral loss in regions immediately surrounding the striate areas. It has led him to the belief that one of the primitive basic functions of the organized nervous system is to mediate generalizations of this sort and that "trans-cortical association" is unnecessary for their proper functioning.

Work with the other senses—for example,

platform from the force of the rat's jump, and the animal lands on top of it on the platform. But the incorrect (negative) card is securely fastened and does not give way when the rat hits it. Consequently the animal falls into a net below. Similar alternations in position of the cards are used to those given in the Yerkes box. The advantages of the apparatus over the Yerkes box are that the stimuli are so presented as to attain greater attention from the animal at

audition, olfaction, etc.—is likewise interesting mainly with reference to the neural mechanisms involved. Other than this the studies have shed little light on the nature of the processes in themselves. Thus the rat can make auditory discriminations based on noise versus silence and is abnormally affected by high-pitched sounds such as key jingling, hisses from air blasts, etc., and can make gross tonal discriminations put out by a loudspeaker from an electric oscillator, but these discriminations are not highly refined. This conclusion should be accepted cautiously, however, in view of our experience with visual figure discrimination. New methods and different apparatus may give more striking results regarding tonal discrimination. In auditory discriminations, the cerebral cortex seems to function much like the visual area for brightness discriminations; large destructions may abolish the habit, which may be reacquired in the absence of the auditory area.

Incidental observation of the rat sniffing about in his home cage or any strange situation would lead one to suspect that the animal utilizes his sense of smell considerably. Indeed, early studies indicated that the animal was assisted in learning mazes by odor trails. However, olfactory discrimination habits involving choices similar to those in vision are not easily acquired, and are subject to criticism regarding the adequacy of control, especially with respect to eliminating the possibility of the taste sense. Recently a discrimination apparatus depending on a food-reaching response has been described. Animals were able to make olfactory discriminations in a way which apparently precluded the possibility of gustatory discrimination. The most significant fact from studies of the neural mechanisms of olfaction is that small, intact remnants of the olfactory bulb are sufficient to carry out discriminations. Destruction of the bulbs must be complete to insure abolishment of function.

Work on the other senses, especially cutaneous and proprioceptive, have been largely concerned with their role in maze learning. For proprioception *per se*, inclined planes have been used. The rat can discriminate relatively fine differences of inclination (approximately 4°). With lesser differences the discrimination becomes progressively more difficult, but some animals can continue to discriminate differences

of 1° in inclination. Other methods have been devised to test the rat's ability to make assorted specialized sensory discriminations—for example, temperature discrimination, visual depth discrimination, etc. In the latter case, animals reared in the dark can make immediate adjustments to various distances, suggesting an integration of organization without need of visual space experience. Except for this kind of study, little work has been done in recent years to add to the general conclusions from such studies that the animal possesses some ability along these lines.

Studies of gross motor phenomena fall under the head of general activity. The most popular apparatus for such work is the revolving drum, although other activity cages suspended on rubber tambours and recording on a smoke drum have been used. In the revolving drum the record is the number of revolutions made as a function of time. A great many conditions are known to influence this spontaneous activity and are summarized by Munn (25). The major influences are both external and internal, some associated with changes in the environment—for example, light and temperature—and some with conditions involving the general body processes and well-being of the animal—for example, hunger, sex, fatigue, and influences regulated by the endocrine glands.

Special motor phenomena include varieties of integrated responses, such as jumping, swimming, coordinated walking on a narrow pathway, preferential handedness, and the like. Since jumping is called for in the Lashley figure discrimination apparatus, such discrimination habits may be disturbed by cortical destructions which interfere with coordinated jumping without disturbance of visual ability as such.

The frontal regions of the brain are concerned with the control of these motor coordinations. Electrical stimulation of the frontal areas of the rat's brain produces movements on the contralateral side of the body. Although there is not the degree of differentiation found in species with more highly developed brains, there is considerable refinement. Thus local areas control fore and rear limbs, head, neck, etc. Within the forelimb region extensor thrusts can sometimes be elicited rather than flexions or salute movements. The area is so small, however, that these different movements cannot be obtained by differential exploration within

the same animal during a given observation period.

The most precise localization of motor function has been reported for handedness. Destructions amounting to one per cent of the total cortical area, and even less, interfere with the use of the forepaw in preferential handedness. These results do not conform to the recent popular interpretation that adjacent regions contribute to the function, with degree of loss proportionate to the extent of destruction in this general region (21). They do, however, conform to the more recent interpretation of Lashley regarding the visual area and trans-cortical regions described above. This precise, localized region is prepotent for the control of preferential handedness. Sub-cortical, trans-cortical and cerebellar mechanisms contribute nothing directly and little indirectly to the control of the function. From the results so far obtained the evidence seems to indicate that any change in handedness would be found in this localized pool of motor neurons controlling this function in the frontal areas of the cerebral cortex rather than in any other central mechanisms. Changes can be effected, for example, by arrangements which will lead to practice in the non-preferred hand. After considerable practice of this sort, some animals show transfer of preferential use when returned to the normal situation. Similar changes have been reported from the application of certain drugs—for example, acetylcholine—to the *homolateral* frontal area, but the results have been somewhat equivocal up to the present.

MOTIVATION AND EMOTION

Since Thorndike's statement of his laws of learning, motivation has come to occupy an increasingly important position in psychology until today it is a central concept (22, 14, 24), yet it is a curious fact that psychologists do not know, or at least are not agreed upon, what they mean by motivation, and the operational point of view, as in most of their broader concepts, does not give them much help. Young (40, p. 87) cites six common points of view regarding motivation: (1) It may be looked upon as a stimulus—physical energy which excites receptor or nerve cells. (2) It may be regarded as a chemical state, like thirst or fatigue, regulating the excitability of cells. (3) It may be a determination to act, an intention, or set,

initiating and channelling bodily movement. (4) It may be looked upon as a tension or force, driving the organism, e.g., libido. (5) It may be related to the doctrine of psychological hedonism which holds that pleasantness and unpleasantness are human motives. (6) It may refer to external situations which arouse action.

The first two views are more common than the others among animal psychologists, and if we say, operationally, that motivation is what psychologists study when they say they are studying motivation, and thus try to abstract the definition from what was done in the laboratory, no one of the definitions fulfills all the requirements. According to Stone (1), "the term *sexual drive* is generally used in comparative psychology to denote aroused action tendencies in animals to respond to objects of their external environment that, in some measure, lead to the satisfaction or alleviation of dominant psychological urges associated with reproduction. Strength of drive is expressed in quantitative terms that describe sexual activities with respect to frequency of occurrence, vigor and persistence, or some other aspect that conveys the idea of quantity or magnitude" (p. 1213). But Skinner (29) regards drive as a hypothetical state between operations and behavior not *necessary* but useful in a descriptive system. It is an organic state affecting reflex strength without altering "reserve" and it is not thus a stimulus. There is no drive for pupillary contraction, since this behavior is relatively invariable. Presumably this view would likewise rule out any drive for the need for oxygen, since reflex breathing is likewise relatively invariable, and ever present. If you look upon hunger as interoceptive stimulation due to stomach contractions, it is difficult to account for the continuation of eating when the contractions cease or at least have been reduced by the first early ingestion of food. According to Skinner, there is not a single hunger, but a series of sub-hungers, akin to appetite, and an animal will proceed with the eating of one kind of food when another has been fully satiated. Although no such sub-appetites for sex have been demonstrated, they would probably be found under proper circumstances. Some psychologists distinguish on a stimulus-response basis between motivation and emotion. Thus emotion is a variety or form of response, while motive or drive is a form of stimulus. For Skinner, how-

ever, emotion is a change in reflex strength brought about by certain types of operations, and, he mentions, there is frequently a thin line of distinction between drive and emotion.

Warden, et al. (36, p. 219), list five methods for measuring drives: (1) general activity method, (2) choice method, (3) resistance method, (4) obstruction method, and (5) learning method. To these can be added what might be called, for want of a better name, the direct method. General activity has been previously described in another connection. The learning method has been criticized for being complex and unsuited to drive measurement. Thus Stone (1) states "the technique is poorly suited to the comparative study of optimal learning rates, because a well-nourished male that has suffered little food deprivation, although manifesting a strong sexual drive, is sluggish on the maze. Likewise, a female that is drastically deprived of food fails to come into heat. At best, the technique has little promise of fulfilling the major desiderata for studies of sexual drives" (p. 1249).

The choice method used, for example, by Tsai in his study of the relative strength of the sex and hunger drives in rats uses a maze-like compartment with two alleys, one leading to each incentive or goal (fig. 7). As he employed it, the method has been subjected to considerable criticism, largely through failure to exercise sufficient control of the strength of each drive at the time the comparisons are made, but a rerun under better control gave essentially similar results, indicating a much greater choice of food over sex by the rat under these circumstances. The criticism that the method complicates the study of drives by taking two at a time seems beside the point. All methods are complicated by an additional variable, the obstruction method, for example, by punishment with electric shock. It involves the choice of punishment with reward to avoiding punishment without reward. Recently Skinner (29) has stated, "The simplest way to determine whether hunger is stronger than sex is to place appropriate stimuli for each drive before the organism at the same time. If it is argued that drives mutually influence each other, so that maximal degrees of two drives cannot exist at the same time, then the question of comparison is academic and may be passed by" (p. 403).

The resistance method and obstruction method

are very similar. In each case the animal is subjected to electric shock in order to obtain the incentive. In the first, the shock is increased until the animal refuses to cross the grid to reach the incentive. The strength of shock is taken as a measure of the strength of drive. In the second, a constant strength of shocking current is used and the number of crossings in a standard interval of time is an index of the strength of drive.

In the early work with the Columbia obstruction box (fig. 8), the method gave great

FIGURE 7—Floor plan of the choice apparatus, used by Tsai. The animal is started at E, with incentives at A and B. The choice is selected at X and Y, with control doors leading to the incentive at D, D' and d, d'.

promise of systematizing the entire subject of motivation. It appeared that the standardization in terms of number of crossings to a constant shock under different motivating conditions and appropriate incentives gave directly comparable measures. Thus it would be possible to rank the order of strength of various fundamental drives. Thirst was stronger than hunger, which in turn was stronger than sex, and all were stronger than "curiosity," an opportunity to explore, in the rat. The finding that the maternal drive was the strongest of all was stated with some reservation, since it depended upon a preliminary investigation based on a small number of cases. The hunger drive increased in strength with food deprivation up

FIGURE 8—Floor plan of the Columbia Obstruction Box. A, entrance compartment; d_1 , door leading to B, obstruction compartment with electric grill; E, release plate for door, d_2 , to incentive at D. to two days for females, and four days for males, after starvation, whereupon it decreased in strength. Likewise, thirst reached its maximum strength one day following water deprivation and decreased in strength thereafter. The male sex drive was strongest 24 hours following copulation and gradually decreased thereafter to 30 days later, as long as the tests were conducted, but the strength of the female sex drive followed the estrous cycle of the animal, independently of satiation following copulation. Early criticisms of such conclusions concerned the interval of time selected to run tests. A 20-minute interval had been selected, and the number of crossings in this time measured the strength of the drive. The original experiments indicated less clear-cut results when approaches or contacts with the electrical current were used instead of actual crossings, but further analyses revealed that different time intervals gave different results, so that the conclusions were a function of the intervals used.

More recently, direct measurements have failed to confirm some of the findings of the obstruction method. Direct measurements have to do with the observation of the actual behavior concerned with the drive in question. For sex it would be copulation; for hunger, eating; and for thirst, the drinking of water. We have already seen that observations of copulatory behavior in the male rat over a three-hour interval required some four days before recovery to complete strength occurred, a figure at variance with the 24-hour recovery period reported for the obstruction method. Skinner (29) worked with the hunger drive as meas-

ured by the strength of the "reflex" which resulted in feeding. In comparing his results to the obstruction method, Skinner writes:

"When the individual curves are averaged, the resulting curve closely resembles that of Warden and Warner, except that the peak comes slightly later. But this averaged curve differs in two important respects from the individual case: the increase in hunger is slower and the final drop sharper in the individual curve, and the height of the peak is greater. Both results follow from the fact that different rats reached peaks at different times. If this was also true, as is probable, in the Columbia experiments, the curve there obtained does not clearly represent either the course of the change in hunger or the maximal value attained. Some of the rats that were starved for four days had probably reached their maximal drive before the test period, and some certainly reached it afterwards. The fourth day happened to catch more rats at or near their maximal drive than any other period used. In the present experiment the animals reached peaks anywhere from the fourth to the thirteenth day of starvation. The mean is at 7.3 days and the median is at 7. By averaging the rates for all rats a peak at five days is obtained" (p. 404).

Enough has been outlined above to indicate that no definition and no one's point of view will be acceptable to all others. In fact, there is enough diversity of views to lead one, unless he is himself concerned with a systematization of concepts, to consider rejecting all concepts of motivation, following the Skinner suggestion already referred to consistently to its ultimate end and study behavior under specialized oper-

ational conditions. If this were done, however, one has the feeling that the concept would probably be conveniently reintroduced when certain types of phenomena were considered, perhaps under a new name, as was done in the case of instincts. In fact, instincts themselves came to be considered as drives, needs, urges, etc. A better procedure would be to recognize a multiplicity of circumstances that would make convenient the acceptance of different conceptions of the nature of motivation, depending on these conditions. At one time it would be convenient to regard the concept as referring to chemical changes producing dynamic effects of a restrictive sort on the nervous system. At another, as external stimulation, a stimulus producing persistent behavior in the organism. Again it could be, following Woodworth's point of view, the influence of activity in progress on subsequent activity, and so on. Fortunately the animal psychologist is spared the need to concern himself for the present with its conscious and unconscious aspects, apparently of great importance to the abnormal psychologist.

A significant contribution to the concept of motivation has been made by Richter, summarized in a recent article (27). His concept is based on Bernard's constant internal environment—an optimal environment for the habitat of living cells, and Cannon's conception of homeostasis. While these men were concerned with the regulation by parts of the organism in maintaining optimal conditions, Richter studied adjustments by the total organism to do so. Thus animals deprived of certain regulatory organs—for example, the posterior pituitary, the adrenal cortex, the thyroid, parathyroid, etc.—responded by an increased ingestion of proper substances to make up for the resulting losses. A striking example is seen in adrenalectomized rats. The sodium metabolism of such animals is completely upset and enough salt is lost through the urine to result in death in a few days. If such animals are given access to 3 per cent solutions of sodium chloride in their tap water, they will increase their intake of it to 10 to 15 times that of normal animals. Along with the increase in demand for salt is an increase in receptivity of the taste buds. Normal rats could detect, by preference tests, one part of salt in 2,000 of water. Adrenalectomized animals were able to detect one part in 33,000 of water. When the afferent nerve supply to

the taste buds is cut, the animals no longer show the increased salt consumption but die.

At first glance these results conform to a chemical theory of motivation and the specific instances cited by Richter certainly fit better here. Of greater significance is the point he makes that drives are created to maintain optimal living conditions. There is no reason to limit them to chemical changes in the organism. One can be physical, another chemical, a third act directly on established central mechanisms, etc. All are functions of complex physico-chemico-organic conditions within the organism. It is hardly to be expected that the complexity of interactions of androgenic substances acting directly through the bloodstream on neural structures would give as clear and simple a picture as changes in pH on localized bulbar structures in the regulation of breathing. In the first case one would expect widespread effects—for example, on the cerebral cortex—to furnish a basis for the contribution of this organ to sex behavior. Some such analogous functioning can be looked for, but awaits future research.

Studies of emotional behavior in the rat have been confined largely to tests which differentiate degrees of timidity, wildness, aggressiveness, and the like. They have not been concerned with the kind of work that is thought of in connection with Cannon's contributions to the subject of emotion. Other types of animals have been used to study autonomic and hypothalamic mechanisms in emotional behavior. In the rat work, the terminology employed is even less settled than for motivation, where at least there is some agreement that the primary biological drives—hunger, thirst, sex, etc.—though possibly interrelated, are distinct enough to be designated separately. A recent summary of the work on the rat has been given by Hall (11).

LEARNING AND THE HIGHER MENTAL PROCESSES

Measured in terms of number of papers or of time devoted to discussion of concepts, learning is unquestionably the most important topic in twentieth-century animal psychology. Since the time of Thorndike's early study up to the outbreak of the recent war, this topic may be said to have dominated the literature. Only in recent years has there been a comparable rise in interest in another subject, namely, abnormal

behavior. Whether this is a sporadic interest or will continue to grow in importance will be determined in the future. Since it is the subject of a special review in this series, the evaluation of its importance will not have to be considered here.

The literature on learning is so vast it would be impossible to do any kind of justice to a survey of it in this summary. Under these circumstances, it is not surprising that there is no accepted comprehensive definition of what is meant by learning. If learning is what psychologists study when they perform learning experiments, then there is no one learning, but learnings, since they perform many distinct kinds of experiments. The psychologist may hold to the faith that these may be reduced to a single fundamental kind of process, but he has failed thus far to convince his co-workers either of this fact or of the nature of the process if there is only one. One might speculate as to what kind of process might lead to such a conviction, at least for a majority of psychologists. A naive attitude would probably select a fundamental neural process. Skinner (29) has argued convincingly against this point of view, and insists that a science of behavior not only can but must stand on its own feet. Yet with the errors in measurement so inevitable in as variable a phenomenon as a living organism, it is difficult for the present-day student to envisage the time when different methods of investigation can be so well correlated as to indicate a fundamental behavior process in operation. Skinner does not deny the importance of neuropsychology, but questions its significance for the problem considered here. He insists that this solution will be found in behavior studies *per se*, not through correlation to underlying neural structures. I presume if the neuropsychologist succeeded in unifying behavioral phenomena by showing its dependence on a fundamental brain process, Skinner would accept the result as a discovery of the first order, but would expect the behavioral inter-correlations to have predicated such a discovery in the first place.

An empirical approach to the subject of learning can be found in McGeoch's *The Psychology of Human Learning* (22). Although, as its title implies, its primary concern is not with infra-human learning, it does refer to some animal work, especially on the rat, and its statements are general enough in their scope

to be a valuable summarization of the principles of learning for animal as well as human subjects. Hull's *Principles of Behavior* (14) presents his well-known hypothetico-deductive approach to the same problems which concern McGeoch. He gives more data on and greater emphasis to animal studies, although the material is confined largely to those studies, mainly from his own laboratory, which fit into his system. The two texts furnish a good comparison for the student wishing to begin his own organization of the subject. Other contemporary points of view are to be found mainly in the journal articles.

For the purpose of getting a start in our discussion, studies of learning may be roughly divided into two classes: (1) Those concerned with factors or conditions which influence the learning process, and (2) those which are primarily designed to shed light on the nature of the process, i.e., theoretical studies. Yet it is true that many of the first kind of study frequently include an interpretation referring to the second type of study, and no sharp line of demarcation can be drawn between them. For example, in recent years few articles concerned with conditions of learning are content to leave the matter there. They almost always include an interpretative section which tries to link up the study with the fundamental nature of learning. Thus the study referred to under Methods (above), devised to separate the influences of practice and effect, includes a brief reference to the significance of these concepts for learning theory. Other recent studies—for example, of transfer of training, distributed practice, reminiscence, etc.—likewise include interpretations of significance from the standpoint of learning theory. On the other hand, for convenience alone, the conditions of learning may be studied without reference to their theoretical significance. Alcohol under intoxicating conditions may disrupt learning and the relation of dosage concentration to degree of disruption may be carefully outlined without reference to the laws of learning. That this may be due to the influence of the substance on some fundamental underlying learning process may be ignored if desired.

There is no agreed classification of the conditions which influence learning, the grouping of each author reflecting his own interests. In an outline of factors influencing the distribution

of errors and various blinds in the maze, Buel (5) listed a total of 93 factors under 13 rubrics. Kreezer's (10) outline divides the conditions into two large subdivisions: (1) biological, with five subheads such as sex and biochemical factors, with further subheads under these, and (2) psychological factors with 11 subheads such as sensory cues, transfer, etc. Tolman (33), though primarily concerned with theory, shows how the conditions affecting learning can be introduced into his schema as independent variables. These are grouped as (1) environmental, and (2) individual difference variables. Under individual difference variables are included heredity, age, previous training, and special endocrine, drug and vitamin conditions. He likewise introduces intervening variables—for example, demands, hypotheses, etc.—but the distinctions are made for theoretical purposes.

The following outline reverses the approach which would fit the conditions of learning into a theoretical scheme. Since theory is in such an uncertain state (disagreeable state, one is tempted to write, since there is so much disagreement among the theorists!) it would seem justifiable to fit it under a classification emphasizing the empirical conditions. Not all of these conditions are listed, but some of the major categories are subdivided further to show how the process can be continued. The only advantage in the present classification is its simplicity.

Learning may be studied as a function of:

- I. Methods of measurement
 - A. Practice
 - B. Performance
- II. The problem
 - A. Type
 - B. Length
- III. Subject
 - A. Species
 - B. Individual
 1. Heredity
 2. Age
 3. Sex
 4. Previous experience
(transfer of training)
 5. Motives and incentives
 6. Physiological conditions
 - a. Sensory
 - b. Motor
 - c. Neural

d. Endocrine

e. Diet

f. Drugs

IV. Environment

A. Wider sensory environment, as light, temperature, etc.

B. Specific to the problem, as maze pattern, etc.

V. Method of learning

A. Distribution of practice

B. Guidance

C. Part-whole

VI. Theoretical conditions

A. Laws or principles

B. Chance

A few words of discussion might be mentioned about some of these conditions. However, since not all of the conditions can be discussed without undue expansion of this article, omissions are inevitable and will occur either where brief reference has already been made (e.g., heredity), where little of recent interest in the topic has been shown (e.g., part-whole methods of learning), or where the literature is so great that a brief summary is impractical in a limited space (e.g., physiological conditions).

Method of Measurement. A good discussion of learning as a function of methods of measurement is given by McGeoch (22). He adopts the empirical attitude that there is no one form of learning curve, and uses a well-known example of measuring progress by two different methods to get, under the one condition, a curve with no acceleration and, under the other, a decelerated curve. He asks why one curve should be called representative of learning any more than another (p. 65). Nevertheless, having standardized the procedure and then obtained a given type of curve, it is in order to investigate further its basis. This is the case with those who study learning curve equations. A discussion of this subject and bibliographical material will be found in both McGeoch (22, Chapter 2) and Hull (14, Chapter 8).

Type of Problem. The question of type of problem and of species can well be discussed together. Evidently, with the wide variety of animal forms at the disposal of investigators, it is not to be wondered that many varieties of problem have been utilized and given to the animals to solve. Obviously a problem must be

selected that is within the possibilities of the organism's repertoire. The rat is so well adapted to maze learning that it cannot safely be said that, as far as this type of learning is concerned, he is inferior to man, but no one would seriously put him in the same class as man for this reason alone. Yet it is easy to assume that other species with less ability than the rat in the maze might be tentatively classed below him in the scale of intelligence because they fail to show equal maze ability. Animal psychologists with a phylogenetic bent, nevertheless, would like to develop such a scale. To include a wide variety of tasks to sample the repertoire for different species is almost an endless task, and even then the relationship of the problems to one another is not established to make comparisons possible. Warden's laboratory, where this attitude prevails, has tried to meet the issue with a specially devised technique that permits progressively more difficult problems of the same series to be set for the animal. The apparatus is called Jenkins' triple plate problem. (See fig. 9.) It is especially adapted to mammals. Results from it would place the rat below the kitten or monkey but above the guinea pig, in the particular ability tested by the apparatus, but it has not been demonstrated that the ability is any more general than the maze or other problem selected for some other specific purpose.

Motives and Incentives. Recent years have seen an increased interest in the influence of motives and incentives in learning. Motives refer to the conditions within the organism (e.g., hunger), and incentives to those goal objects (e.g., food) directly related to particular motives. Many psychologists have shifted their emphasis about these factors as a consequence of the relation of the factors to the law of effect or principle of reinforcement. Motives and incentives to them have become not conditions listed with a number of others such as drug or temperature conditions, but necessary conditions without which learning would be impossible. Thus a recent introductory text (28) in general psychology states that "theoretically, at least, it is quite clear that learning will not occur in the absence of a motive" (p. 293).

Statements like this may imply more than their authors intend, but their import seems to make something special out of motivation not

to be found in many of the conditions influencing learning. Of course, the saving phrase may be "theoretically at least." *Theoretically at least* many of the conditions of learning listed above are essential to the process. Thus one cannot have any learning without an organism, nor without a subject matter or problem. Likewise, some method of learning must be adopted; there must be some kind of distribution of practice, bunched or otherwise, in order for learning to

FIGURE 9—Floor plan of the Jenkins triple plate problem. Plates which must be depressed in proper order to open the door, D, are shown at 1, 2, and 3. The dotted line shows the path followed when the plates must be depressed in order 1, 2, 3, 2, 1, to reach the incentive. Redrawn from Warden, Jenkins and Warner, Vol. 1, p. 252, New York, The Ronald Press Co.

be possible. Even the temperature cited under environmental factors cannot be absolute zero (theoretically at least) or there would be no learning. About the only thing unnecessary listed under these conditions is theoretical factors. You don't need to have a theory of learning to make learning possible.

What then is meant by emphasizing motivation in learning? There is the possibility that motivation permeates all through the process and may intervene almost surreptitiously when

other conditions are seemingly being investigated. For example, an early study of the effect of age on maze learning in rats indicated that efficiency increased with age to 75 days and thereafter decreased to the limits of the study. These and similar clear-cut results showing a superiority for younger over older animals have been criticized for failing to control motivation. It is argued that younger, growing animals are apt to be more strongly motivated by hunger, the motive usually employed in maze learning problems, than older, fully developed animals. Presumably, the degree of motivation should be controlled before results for different ages can be compared.

It has never been clear to the writer just what is meant by control here. It is suggested that maximal motivation should be employed. Why? Since we cannot measure motivation directly in individual animals under these conditions, who is to say that maximal motivation in 75- and 700-day-old rats are equal? Why should not normal motivation be selected, in the sense of the normal environment used in genetics and how are we to know if this is constant at different ages? Assuming that it is, are we sure this is what is desired? It would appear that analysis of variance offers the solution desired in this problem to separate the effects of motivation and age, providing that some standard method of measuring motivation is acceptable, e.g., hours of starvation. The experimental design could then test the significance of age differences after motivational differences are removed from experimental error. Until this is done, age can only mean, operationally, all the influences affecting an organism during time, including maturation, senescence, experience, *motivation*, and whatever else anyone can think of to include. Age is merely a convenient measure of the multitude of things that can happen during passage of convenient amounts of time.

At least this is an indication of one way of considering the ubiquity of the motivation problem, but this point of view would apply to any of the conditions above if enough were known of them and of their influences on the organism. Another type of consideration falls under theories of learning. In all likelihood most psychologists who emphasize motivation have in mind a particular theory of learning. In 1941, in a special Military Psychology number in the *Psychological Bulletin*, Mowrer (24) sum-

marized the present status of theories of learning, aiming to avoid controversial issues and to outline agreements among psychologists as a basis for concerted action in a national crisis. After quoting Thorndike's statement of the law of use and the law of effect, he writes:

"The Law of Use has been shown to be invalid. . . . The first half of the Law of Effect has become the basic formula for all learning. . . . Investigators who have largely restricted their study of learning to the development of anticipatory responses have, in general, accepted the 'association' theory of reinforcement, i.e., they have tended to assume that the active agent in learning of this kind is mere 'temporal contiguity' or 'paired presentation' of the sign (conditioned) stimulus and the signified (unconditioned) stimulus. It is true that temporal contiguity of the two forms of stimulation is a necessary condition for the occurrence of learning of this kind, but it appears not to be the sufficient condition" (pp. 424-426).

In favor of his point of view which gives fundamental importance to the law of effect in learning, he cites the advantage that this hypothesis considers learning "intimately related to the factors of motivation and motivation-reduction, a prerequisite of any theory that is to square with common sense and clinical observation" (p. 427).

Without desiring to reintroduce controversy where broad agreements are already established, but in fairness to the reader I cannot refrain from citing evidence from another leading psychologist who, curiously (from the standpoint of broad agreements!), is associated with the same university as Mowrer. In Murchison's Handbook (26), Lashley stated that "the law of effect confuses learning with performance," and "the evidence suggests that the drive is one of the associated elements in the maze habit rather than the agent responsible for the association" (p. 486). Later he wrote (19) that "Temporal contiguity is the only one of the 'laws' of learning which approaches universality. Not all simultaneous activities of the nervous system become associated, but apparently some temporal overlap is essential" (p. 317).

If there is one thing non-controversial writers would seem to be able to agree on it is that learning theory is the most controversial topic in the whole subject of learning. No review can hope to do justice even in outlining the points

of view. Peace makers who enter the subject in hopes of reaching a compromise or resolving the disagreements or confusion are apt to find themselves quarreling with each other over the nature of the difficulty. The best source of this confusion is the Psychological Review where a running account of the controversies is carried on. Until more agreement has been established, it seems appropriate to relegate the concept of motivation in learning to its proper place as one of many conditions influencing the learning process, not the *sine qua non* for all learning.

Theoretical Conditions. From a consideration of the place of motivation in learning we are thus led to the topic, *theories of learning*. From what has already been outlined the reader can expect not even an approximation to unity of opinion regarding theories. One would like to write that there are two or four or even a dozen theories, differing from one another in certain fundamental principles or in this or that detail, but such an attempt would be bound to overlook someone's valid point of view (from his point of view!). Only one thing can probably safely be said concerning classification of theories—there are some who are for and support a given theory and others who oppose it in one way or another. The statistically minded psychologists might wish that a record could be kept to see how the voting went on a given issue. Unfortunately many psychologists fail to register and are, therefore, unheard respecting their attitude, but if they could be aroused or required to declare themselves, this much could be asserted concerning the outcome. No theory would pass the 5 per cent level in acceptance as is commonly demanded in significance for experimental results. This is not meant to advocate that adequacy of scientific theory can be determined by unanimity of acceptance, but rather to emphasize the unsettled state of contemporary learning theory.

Of all theories, however, none would have wider acceptance probably, unless they be those centered about Thorndike's law of effect, than do those concerning conditioned reflexes, and some theorists have tried to combine them into a universal theory, for example Hull (14). For such theorists, conditioned reflexes are considered in one sense or another as the prototypes of all learning. The details can be traced historically beyond the terminology "conditioned

reflex" to British associationism, but will be ignored here. It was Pavlov who first employed the modern terminology, and who is accredited with the early objective studies of the phenomena. Later writers came to prefer the term "conditioned response" as a first step toward broadening the concept to include other varieties of learning behavior, e.g., what has sometimes been termed Thorndikian responses, which did not meet all the criteria of the relatively invariable, circumscribed, precise reflexes studied in physiology. Recently Skinner (29), who has no terminological inhibitions, has reintroduced the term *reflex*, applying it even to these Thorndikian responses and divorcing it from its neurological connotations. On the other hand, Tolman (33) would claim that Skinner's variety of response is not a reflex at all, and we can foresee the possibility of a terminological quarrel which would prevent the discussion of the phenomena and their significance for learning theory.

Extended treatments of the subject are to be found in Hilgard and Marquis (13) and Hull (14). Although both books are concerned very extensively with examples of rat learning, one is struck as a first impression with how little of the work deals with rat conditioning of the Pavlovian variety. Recalling Munn's statement in 1933 that the conditioned reflex method has not been used in discriminative learning in the rat, we may ask just what its status is for this animal.

In 1932 Warner reported conditioned responses in the rat. If the animal is placed in a box with two chambers divided by a partition that the animal can jump over to get from one chamber to the other, and if the box is wired to shock the animal, conditioned avoidance responses can be established. Warner points out that the established responses are quite different from early responses to the shock, but this feature has been reconciled by recognizing that the conditional salivary reflex is likewise not a replica of the unconditioned reflex e.g., in viscosity of saliva, etc. A variation of Warner's method has been studied in considerable detail by Hunter. Nevertheless, there may be enough difference in methodology in Pavlov's and Warner's situations to justify Woodworth's classification (39) into three types: (a) the conditioned response neither produces nor avoids the unconditioned stimulus (Pavlovian

variety); (b) the conditioned response escapes or avoids the unconditioned stimulus; (c) the conditioned response produces the unconditioned stimulus (pp. 102-107). An example of type (c) has been referred to above as the Thorndikian response, and is exemplified by the bar-pressing behavior seen in the Skinner box. Our question is whether the type (a) response has been studied in the rat. The closest approach to it is the work of Schlosberg et al., who have had moderate success (?) with eyelid, tail and foreleg reactions. Their chief finding, however, would seem to be that the rat represents a species for which classical or Pavlovian conditioning experiments are not very suitable. Liddell (15) has emphasized differences in animals to conditioning procedures, individual, race, and species differences, and the rat would seem to represent an extreme example of a species not very amenable to this "physiological" study of conditioning.

Only if we are ready to accept types (b) and (c) as instances of conditioning to which the general principles evolved from type (a) conditioning apply, can we accept a conditioning theory of learning. This has been most systematically presented by Hull (14). One is impressed, to say the least, not only by his rigorous, careful thinking on this subject, but also by the ingenuity of the experimental work carried on by his students in testing his hypotheses. Hull states the fundamental law of conditioning as follows:

"Whenever an effector activity occurs in temporal contiguity with the afferent impulse, or the perseverative trace of such an impulse, resulting from the impact of a stimulus energy upon a receptor, and this conjunction is closely associated in time with the diminution in the receptor discharge characteristic of a need or with a stimulus situation which has been closely and consistently associated with such a need diminution, there will result an increment to the tendency for that stimulus to evoke that reaction" (p. 98).

It will be seen that this is a double-barreled statement, including what was previously covered by the laws of contiguity and effect. Hull also gives a lucid account of the principle and its relation to contiguity and effect, especially in the notes at the close of chapters 6 and 7 in his book. The process is illustrated and described in fig. 10, taken from his book.

Hull's principles have been subjected to a searching criticism by Leeper (20). Since this in itself occupies 49 pages of print, I can only refer to his discussion of the principle that reinforcement is essential for learning. According to him, this principle is insufficient to account for the results of latent learning and differential motivation (pp. 35-38). Our purpose is achieved by illustrating differences of opinion on the subject.

It would appear that one's point of view and particular bias *before* he begins to study conditioning will determine his evaluation of the phenomena for learning theory. If he has a strong mechanistic-peripheralistic tendency plus a desire to arrive at some kind of simplification of an inordinately complex subject—even if this be somewhat in error—he will be favorable to the program. If he has Gestalt-configurational-perceptual or central trends or biases, he will be skeptical. The first type of individual will elaborate in great detail the mathematical symbols and exercise great care in drawing the deductions for further experimental work. The second will counter with: But don't forget to include in the equations a wide-awake, intelligent animal with an efficiently functioning nervous system. Empiricists—if there are any remaining after reading this far—will be ready to place theories of learning in a subordinate position among conditions of learning, as was done in this outline, and be content to conclude that for the present there are no established principles worthy of the name.

We have considered conditioning from the standpoint of its relation to learning theory. It should be pointed out that the phenomena can be studied without any such reference, and that many results can be obtained of great interest from other points of view. As an example of this the reader is referred to the work of Liddell, outlined in recent summaries (15, 23). He writes: "During the course of our study of conditioned reflexes, from 1927 to the present, I came to believe that Pavlov's method of the conditioned reflex could be accurately characterized as a method for producing the experimental neurosis" (15, p. 391), and has accordingly emphasized this point of view in his study of the phenomena of conditioning. His work, however, has not used the rat as a subject. Another investigator, Harris (12), has used the rat in a study of conditioning of Woodworth's type *b*, avoidance conditioning, with reference

FIGURE 10—Diagrammatic representation of the process of strengthening or reinforcing the connections between $S_D \rightarrow R_4$ and $S_A''' \rightarrow R$. The step-like rises and falls of the several horizontal lines such as those of D and S_D , the shock to the tissue and S_D , represent the rise from zero and the fall of the respective processes. The arrows with wavy shafts represent a physical causal relationship other than by way of receptor-effector stimulus evocation. Thus the rise of the current on the grid (S_D) causes the shock to the tissue of the animal's feet, the response of the receptor in the skin (S_D) of those regions, and the drive (D) or motivation to action. The separation of the foot from the grid by the act of jumping (R_4) terminates simultaneously the injurious action or need, the receptor discharge (S_D), and the drive (D), though the current on the grid remains unchanged. It is the reduction in the drive receptor impulse (S_D) and the drive (D) which are believed to be the critical factors in the process of reinforcement. The arrows with solid shafts (\rightarrow), whether curved or straight, separate or jointed, represent receptor-effector relationships in existence before the learning process here represented occurred. The arrows with broken shafts ($--\rightarrow$) represent receptor-effector connections here in process of formation. Distance from left to right represents the passage of time. Description and figure taken from C. L. Hull, *Principles of Behavior*, New York, D. Appleton Century Co., 1943, by permission of the publishers.

to such concepts as habituation, pseudo-conditioning, and facilitation.

As opposed to the conditioned reflex analysis of learning processes one might outline the point of view of other psychologists, for example Tolman or Lashley. Although Lashley has never been primarily concerned with the establishment of a complete and consistent theoretical account of learning, the results of his experimental work, especially of the relation of brain processes to learning, has led him to be critical of the over-simplification which he feels results from conditioning or similar theories. He was largely responsible for the theoretical account outlined in Watson's early book (38, chapter 7), and his experimental program on the neural basis of learning was established to test the principles outlined there. These principles, of course, emphasized the factors of frequency and recency. In a controversy with Hunter over the interpretation of his experimental work, he has pointed out that it is as if he had diabolically planned to have the system tumble like a house of cards as a consequence

of his experimental results. Since then he has entered into the controversy on other occasions, for example, in his test of the "continuity theory" (18), and also in his criticism of Pavlovian cerebral theories. In a recent article (19), he points out how the Pavlovian theory of generalization based on nervous irradiation in the cerebral cortex fails to meet certain types of problem calling for explanation, for example the problems of stimulus or response equivalence. In this connection he outlines a suggestion of his own with a diagram in explanation of it (fig. 11).

"Visual fixation can be held accurately for only a moment, yet, in spite of changes in the direction of gaze, an object remains the same object. An indefinite number of combinations of retinal cells and afferent paths are equivalent in perception and in the reactions which they produce. . . . The first experience of a stimulus excites a certain number of neurons in a definite pattern (see fig. 11 bc-f). An associated reaction (y) is formed as a result of this stimulation. Thereafter, the excitation of any

FIGURE 11—Diagram for the problem of stimulus equivalence. The response, y , is associated first with stimulus pattern $bc-f$, later with an equivalent pattern, $ce-k$. A fixed, localized trace, indicated by the heavy lines, cannot account for the reaction to equivalent stimuli. For further discussion, see text. From K. S. Lashley, "The Problem of Cerebral Organization in Vision," p. 305, in *Biological Symposia*, Vol. VII, Lancaster, J. Catell Press, 1942. By permission of the publisher.

similar patterns of neurons ($ce-k$) will elicit the associated reaction. The later stimulation need not, and practically never does, involve the original combination of sensory cells. It preserves only certain proportions or relations among the elements of the stimulus pattern" (pp. 304-305).

If it is assumed that a trace is left by the first stimulation to determine later reactions, the difficulty is to localize it. If it is localized in the neurons involved in the first reaction, they apparently do not need to be reactivated to elicit the same reaction. Hence Lashley suggests that the whole system takes on the influence of this trace, and it is the pattern, not the element,

that counts. Yet nerve impulses are transmitted over restricted paths. Their numbers can mount up to millions and more.

"The receptive layer of the visual cortex, in an animal even so primitive as the rat, contains half a million cells, all of which are subject to continuous excitation from the retina, and this half million serves only to initiate the chain of cerebral activities. In any such system the contribution of a single nerve cell can have little influence upon the whole. Behavior is essentially the statistical outcome of nervous activity" (pp. 310-311).

Is there a weakness in suggesting that there can be a first experience of a stimulus to excite

a certain number of isolated neurons in a definite pattern? This first experience may itself be a statistical outcome from a large number of variable elements, and in terms of the diagram (*bc-f* arousing reaction *y*), the "visual" elements never existed except as a statistical outcome of neurological elements. When such diagrams are put on paper (for conditioning theories or any other theory), it is always implied that *bc-f*, or whatever symbols are used, stand for something in the way of an element. Thus *b* would be one rod cell in the retina with its connections, ultimately leading to *y*; *c* is another rod cell and *f* still a third. From what is known of individual receptor cells and their activities, the time relations of the discrete activities of any single cell are so much smaller than the time relations of a "first experience" as to be of a different magnitude altogether. Thus the activity of cell *b* in accordance with the all-or-none law and the upper limit of frequency of nerve impulses, and likewise of cell *c*, and all others, are themselves statistical outcomes during "a first experience." One can be very sympathetic to his suggestion that the correlation of behavior to neural elements requires such a statistical analysis without requiring static neural elements with which to begin the analysis. In this way, an apparent paradox may be avoided. The system was in operation as a dynamic statistical flux before the rat ever looked at the triangle versus the circle to begin with, and when that "first look" came, it was imposed as further dynamic statistical events, upon some on-going processes in any specific cells, for example *bc-f*. The most completely systematic elemental approach to the subject would seem to be found in conditioned reflex theories as developed by Hull. If one has no faith in this, the most consistent alternative would avoid elementalism at the very outset. My own faith is that neurological omniscience would verify such a statistical analysis and as a consequence the problem of the fundamental nature of the learning process can be solved only by understanding the mechanics of the nervous system, only by knowing what goes on underneath the skin of the animal. Until this is realized, psychologists will continue to differ on the fundamental principles of learning, and no amount of careful, detailed studies which are restricted to the control of the environment will give us that insight.

Higher Mental Processes. Emphasis on what goes on underneath the skin of the animal deserves some support from behavioral studies. This can be found, I believe, in two directions: (1) a consideration of higher mental processes; and (2) laboratory experience in animal work. As to the first, what is referred to has been called by Heron (23) complex learning processes and includes insight, reasoning, delayed reaction, alternation problems, and generalizing, among others. Of these, greatest attention has been given to insight problems and the delayed reaction. The latter delineates more sharply than most of the others what is meant by "com-

FIGURE 12—Floor plan of the delayed-reaction apparatus. The animal is restrained at R, while the light, L, shines through one of three openings, O, and food is at D. Only if the correct choice is made after the delay will the animal be rewarded with food. From F. A. Moss, *Comparative Psychology*, p. 258, New York, Prentice-Hall Co., 1942, by permission of the publisher.

plexity" or "higher mental processes." It could turn out, of course, that an understanding of the neurological basis of the reaction would indicate it to be actually simpler as to the essentials of its neural functioning than associative learning or the acquisition of an act or skill. Or it might be that these are all instances of the same basic mechanism, as most theorists are inclined to believe.

The delayed reaction was first devised to test for the possibility of ideas or, as they are termed today, representative factors, in animals. As originally performed, by Hunter, the animal is placed in a box with three compartments one of which contains food (fig. 12). A lamp in each compartment can light up the doorways and on any given trial only the one containing

food is lighted. The animal first learns to select the lighted compartment. The delay is tested by restraining the animal while the light is on and then removing this cue. If, after a lapse of time, the animal can still choose correctly, something must have functioned to direct him in the absence of the cue. This could be gross orientation or some other peripheral mechanism, but if these are ruled out, the evidence indicates some "central" factor is operating.

Early work suggested that the rat could not succeed without body orientation, but later investigations employing variations in method indicated some ability in this regard. Some authors, indeed, have reported delays of several hours, but their methods have been criticized as to whether they involved the essentials of a delayed reaction as outlined above. With other variations in method, 5-minute delays have been reported. Interruptions of peripheral orientation did not affect this ability, but small frontal destructions of the cerebral cortex seriously interfered with it.

It must be granted that the rat's ability in reactions of this sort is extremely limited, and it is probable that we are working near the upper limits of the animal's ability, as some writers have maintained. Animals higher in the phylogenetic scale show much greater capacities in delayed reaction tests than rats, and, as we ascend the scale, progressively greater capacity is shown, lending confidence to the presumption that the test is concerned with ideational or central representative processes. Nevertheless, the fact that the rat can perform successfully after short intervals of delay and that this success is not necessarily dependent on peripheral orientations, points to some kind of central control for this organism, as well as for higher animals. Its gross localization in the frontal areas of the cerebral cortex suggests that future investigation of the reaction should concentrate on this region rather than on peripheral or environmental areas.

Many criteria have been suggested for behavior characterized by insight. The more objective of these are frequently inapplicable and would sometimes fail to apply to some apparently valid instances of insight. To the writer insight has always seemed to be an anthropomorphic term. This is not meant necessarily to discredit the concept. It is easy to find instances of insightful behavior if one wants so to inter-

pret it. All he needs is a little first-hand laboratory experience with animals. If rats are trained in a latch box to press a lever opening the door of the food compartment, their early training looks like trial and error. As the training progresses, they show insight. For example, they will depress the lever, enter to the food compartment and begin eating. Then they will frequently stop up short, run back to the starting compartment, rise up on their hind legs, cock their heads, look at the lever, depress it a few times, in the meanwhile looking down at the door, perhaps depress the lever again, re-enter and eat some more, only to repeat the performance after a brief interval. During such performance, rats have an alert, intelligent look about them. Unfortunately, so does a spring robin looking for a worm. Perhaps they are both showing insight.

If the latch box is so arranged that the preferential use of the paws is employed, the skill of performance can be easily interrupted by a localized destruction of the contralateral frontal cortex. Then the animal will look up at the lever—intelligently, of course—but will be unable to manipulate it to open the door. Such an animal will usually transfer after some struggle to the other "hand" and thereafter increase his skill in manipulation. But if this circumscribed region is left intact but extensive destructions to the remaining cortex are made, the animal may not show very "intelligent" behavior. It wanders aimlessly about the confinement compartment, cleans itself, sits in a corner although hungry, looks through the door, etc. If retraining is resorted to, it might re-learn to open the box and does so with the hand originally used, and apparently with as much manipulatory skill as it previously showed.

Such differences in behavior from cerebral injuries are consistent with the distinction between learning and performance, a point of view which, though widely held, is not universal among psychologists. But it also illustrates the need for more information and better concepts before we can hope to understand the complexities of behavior processes. Only a little laboratory experience is needed to multiply instances of this kind. We may employ terms like attention, perception, comprehension, insight, but about all we mean is that we ourselves don't have much of it in our understanding of what is going on in an animal *experi-*

encing the "brave new world" given to it by experimentalists.

Recent years have shown an increase in interest in other concepts than learning and problem solving of the sort discussed above, where the rat has been used as a subject. Among these are studies of regressive and conflict behavior, examples of which can be found described in the articles by Mowrer and by Miller in Hunt's recent handbook (15). Many of the distinctions brought out in these studies are of great interest for the light they shed on these same concepts in abnormal psychology. Likewise, a recent study has shown that the rat is a suitable subject for certain varieties of cooperative problem solving and that two animals can work together to reduce the possibilities of shock when only one at a time can eat while avoiding the shock. Such work should likewise be helpful in shedding light on some of the concepts of social psychology.

While the outline given above has promoted an empirical point of view it has not been consistent. It has omitted many of the interesting empirical or experimental findings which have been made on the rat in recent years. The vast literature on this subject would have required a book of such summaries rather than an article. And if interpretations and evaluations of all of these studies had been included, this brief outline could have expanded into a set of volumes.

The literature in animal psychology will remain in its present somewhat haphazard and heterogeneous state until some more satisfactory general principles, especially as regards neural functioning, are discovered. It is unfortunate that this field is not in the position of some biological sciences, for example, heredity, which can offer a well-organized theoretical basis and present its experimental results around these principles. However, animal psychology is not alone among the biological fields which are so situated at present, and the fact that it is in this position should offer a challenge to any genius who is looking for new fields to conquer.

Tolman (34) has very recently offered what sounds to me like an apologia for rat psychology tainted slightly by the suggestion of an inferiority complex for not studying human beings in a social milieu. This to me is unnecessary. If the work described above cannot be

justified, it is difficult to see how any general experimental psychology can be justified. Meanwhile, the animal psychologist should guard against a too ready carry over from his experimental situations to human living conditions. When I was a graduate student, a popular book in our subject was Herrick's *Brains of Rats and Men*. We sometimes amusingly quoted its last sentence: "Men are bigger and better than rats," and agreed then, as we can today, that at least 50 per cent of that statement is correct.

GEORGE M. PETERSON,

RECEPTORS AND EFFECTORS: THEIR FUNCTIONAL CHARACTERISTICS.

The Response Mechanism. Living organisms explore the environment and make adaptive responses to it. This general biological process is brought about by a chain of dynamic events in an intricate system. The general character of this chain of activities has

been scrutinized, and the essential nature of the involved functional mechanism revealed.

The environment is explored through the receptors or sense organs. Adaptive responses are eventuated through the effectors or muscles and glands. The receptors and the effectors, although often widely separated spatially, are functionally unified through activities in the nervous system. Whether the coordination be highly complicated or less involved, the nervous system provides a means for the remote control of responses suited to the more or less complex momentary situation. The way this is accomplished is best conceived through a descriptive account of the underlying functional mechanisms.

Receptors are the first structures to be involved in the eventuation of a response to the environment. They differ in kind so as to react to a diversity of stimuli, being specialized with respect to different kinds of physical energy. The photoreceptors respond to radiant energy, the phonoreceptors to vibratory stimulation, the chemoreceptors to chemical action, etc. The organism is equipped to effect adaptive responses to diverse environmental conditions through its differentiated receptive organs.

Receptors are often classified on the basis of the general kinds of function which they serve. Those activated by physical energy emanating from a somewhat remote source are called exteroceptors. The more highly specialized of these are strategically located in pairs, and equipped with muscles that aid in the reception of the energy arriving from objects at different distances. Simpler in construction and scattered widely in the tissues of the body, either singly or in clusters, are the receptors that are known as interoceptors. These receptors respond to mechanical, thermal, and chemical changes in local regions within the organism. Receptors that are activated during walking, running, etc., when tension is impressed upon them in situ in the muscles, tendons, and joints are designated proprioceptors. Although different kinds of receptors are subsumed under each of these categories, and many differences regarding their modes of action are known, the general function of the receptors is directed to the eventuation of a response.

A receptor is a collection of epithelial cells specialized so as to register a characteristic receptor action in the presence of a given kind

of energy. In the more highly specialized receptors, the receiving unit is a mass of intimately associated epithelial cells and is designed to respond to energy of a relatively restricted character. The total receiving unit is connected with its primary center in the central nervous system through a system of many afferent nerves. Through the activities occasioned in the receptor is initiated a sequence of dynamic events through which the nature of the environment is indicated.

Being differently activated, the receptors of the organism comprise signalling systems for diverse kinds of environmental change. The current view regarding mode of activation in principal receptors is essentially as follows. The receptive unit in the *taste* bud is set into activity through chemical interaction between substances conveyed in solution through the taste-pore and other substances stored in the epithelial cells. The *olfactory* receptor is excited through chemical action when volatile particles, borne through the air into the nasal passages, become dissolved in the mucous fluid that over-spreads the small area in which the branches of the first cranial nerve terminate. In the presence of vibratory stimulation, the *inner and outer hair cells* distributed along the spiral lamina of the cochlea respond selectively to the characteristics of the disturbance occasioned in the endolymph by the alternating action of the system of membranes and ossicles in the middle ear. Substances that are derivatives of carotene are stored in the outer terminals of the *retina*, and the energy afforded when radiant energy is absorbed acts so as to occasion photochemical and chemical activities. The tension that is impressed during muscular action upon receptors located in the *muscles and tendons* sets up activity in the proprioceptors. Through its differentiated receptive structures, the organism is enabled to cope with a diversity of environmental changes and to respond to a variety of conditions.

Activity in the receptor is antecedent to and initiates activities in the supplying afferent nerves. The way in which activities in the receptors excite those in the nerves has not been fully elucidated, although the photochemistry of the retina and the cochlear microphonic are presumed to constitute manifestations of receptor activities through which activities in afferent nerves are initiated and sustained. Evidence

obtained through electrical recording techniques reveals that definite quantitative relations exist between the intensity or area of a stimulus and the activity in the nerve, so it may be assumed that the receptor converts some aspect of the external energy of the stimulus into a pattern of neural energy. The pattern of neural energy is propagated over nervous pathways to the primary center in the central nervous system.

Afferent fibers differ somewhat in size, and this difference is believed to determine differences in the rate of nervous conduction. The sensory nerves which supply the receptors in the skin include three types. The large myelinated fibers have a conduction rate of 100 to 5 meters per sec.; the smaller, less heavily medullated fibers conduct at velocities between 14 and 3 m. per sec.; the very small, unmyelinated fibers conduct at rates varying between 2 and 0.6 meters per sec. Fibers in other sensory systems are also differentiated to some extent in respect of fiber diameter. The efferent fibers also exhibit differences in diameter measurement, depending largely on the kind of muscle which they supply.

The situation which constitutes a stimulus to a given receptor usually is not very homogeneous. The incident energy emanating from a local part of the environment is differentiated from that coming from the immediately surrounding parts. This differentiated field of incident energy establishes differing activity characteristics not only in different parts of the receptor field, but also in the afferent system of nerves which is connected with the primary nerve center. During a sustained presentation of a variegated stimulus, physiological gradients are induced in the primary nerve center through the differentiated input of activities in the total system of afferent nerves.

Nerve activity involves certain organic changes. The nature of some of the changes has been brought to light through studies in which the functional properties of nerve during activity and during quiescence have been compared. Although further biochemical analysis will be needed before the involved functional mechanism is thoroughly understood, the information that already is available provides definite insight into the nature of events which provide for intercommunication between the receptors and the effectors. During stimulation in a receptor field, the activated nerves con-

sume oxygen more rapidly, yield carbon dioxide in greater quantity, and produce more heat. It has also been shown that in autonomic nerves at least, acetylcholine is produced both at the synapse and on the neuronal surfaces. Other indications that chemical by-products accumulate in the nerve during the time that the nerve is involved in activity are found in the observation that, during sustained stimulation at constant intensity, the length of the refractory period of the nerve increases many-fold. This decline in the capacity of the nerve to conduct during continued activity may be presumed to be due to an accumulation of chemical by-products which affects the rate of recovery in the nerve immediately after each discharge.

Further details regarding the organic changes which are involved in nerve conduction are needed before a complete specification of the dynamics of nerve conduction can be rendered. In spite of persevering and discerning study, the depths of this problem have not yet been fathomed. However, certain theoretical conceptions have been projected that may serve as guides to future workers. One of the most suggestive of these is the membrane hypothesis. According to this conception, the membrane of the nerve in the resting state is impermeable, with negative and positive charges organized in an orderly way, the negative ions on the inside and the positive ions on the outside of the membrane. During stimulation, however, the local activity in the receptor gives rise to a wave of activity which depolarizes the membrane as the wave of activity proceeds along the nerve. At a given instant of time the membrane is locally rendered semi-permeable and the two kinds of charges become intermixed. The recovery period, which sets in just after the wave of activity has passed, involves *inter alia* the restoration of the original orderly distribution of ions along the membrane. This conception of the mechanism of conduction is a tentative statement and may presently be found to represent a part of a more complete description of the complex chemical changes that are involved in nerve activity.

Through an involved sustaining mechanism embracing interchange among the respiratory, alimentary, circulatory, and neuromuscular systems, the receptors are automatically maintained in a state of readiness to respond, the nerves in readiness to conduct, and the effectors pre-

pared to react. In this way the materials utilized in receptor activity, in conduction, and in muscular action are supplied as needed. The time required to replace these materials is known as the recovery period. Understanding regarding the diverse modes of interchange which take place among nervous, muscular, respiratory, alimentary, and circulatory systems is essential to a thorough-going treatment of the means of intercommunication which normally is maintained between receptors and effectors.

THE PHOTORECEPTORS

The photoreceptors are assumed to be the rods and cones, the outer terminals of the nervous network which is the retina. These structures contain derivatives of carotene, photopigments sensitive to light. Several of these substances are present in the cones, and the special one found in the rods is called rhodopsin.

During irradiation, the photopigments absorb some of the radiant energy, giving rise to a dual response: an initial photochemical reaction coupled with a secondary reaction. The latter is catalysed by the substance formed in the initial reaction but has the thermal characteristics of an ordinary chemical reaction. Analysis reveals this complex reaction to comprise a cycle, *viz.*, rhodopsin is first broken down into retinene and protein, one portion of the retinene being resynthesized into rhodopsin while the other portion is undergoing conversion to Vitamin A and protein. The Vitamin A is relatively instable and also is ultimately resynthesized into rhodopsin. The functional economy of the cones is sustained through a corresponding cycle in which *e.g.*, iodopsin is converted into a different retinene, which in turn is converted into a different Vitamin A and protein, with a portion of the retinene and practically all of the Vitamin A being resynthesized into the original photosensitive substance. Since several photopigments are present in the cones, it is conceivable that as many distinct cycles occur as there are distinct photopigments. Owing to their greater complexity and to their greater imperceptibility, the reactions in the cones today are less well understood than are those which occur in the rods.

The activities which are eventuated in the rods and cones when radiant energy is absorbed by their photopigments constitute the necessary condition for the propagation of neural impulses

throughout the visual mechanism. The mode of neural transmission in the visual mechanism depends upon the nature of the nervous connections which are laid down among the neural elements. In the retina these connections provide for a dual visual mechanism. One of these is illustrated by the kind of connection that is provided in the fovea and which is basic to clear vision, the other by the kind of connection that obtains, in general, in the parafovea and which underlies diffuse vision in faint light. In the fovea each cone is individually connected with a midget bipolar and a ganglionic cell (private line plan) and the elements lack interconnecting branches. However, in the parafovea, groups of rods or cones (or both) collect into each mop and brush bipolar and their inner processes and branches provide connections with a number of ganglionic cells (Polyak).

The way in which activities are functionally interrelated in different parts of the visual mechanism has been zealously investigated recently by a host of scientific workers, chiefly through the technique of electrical recording. The continuity of activities is not easily detected, however, through a comparative study of the action potentials that have been obtained from the retina, the optic nerve, and the visual cortex. The clarification of this intricate neurophysiology depends upon the development of techniques by which the continuity of neural events can be more definitely revealed. Many studies have served to show that summation and inhibition occur in the cortex under given conditions of stimulation. Others have shown that a lawful relationship exists between quantitative variables of the stimulus (intensity, extensity) and the character of an index response, e.g., latent period. The latter suggest that, to some extent at least, the nerves in the complex visual system subscribe to the general laws which govern activities elsewhere in individual nerves. Further details regarding the neurophysiology of the visual mechanism are sorely needed to clarify many of the visual functions which have been investigated with much painstaking care.

Although the reception of radiant energy in this intricate neural mechanism depends primarily upon energy absorption in the photoreceptors, several special ocular mechanisms are utilized as aids to the reception of light. The light reflex, for example, serves to control the amount

of energy that is admitted through the pupil. When the luminous flux penetrating the pupil is increased, the pupil constricts; when the light density is decreased, the pupil dilates. When highly illuminated, the pupil narrows down to a diameter of about 2 mm., while in very faint light the diameter of the pupil may increase to about 8 mm. The variable aperture through which light is admitted into the eye is reflexly governed by two sets of muscles in the iris, one with the muscular elements running around the pupil which acts as a sphincter, and the other with the muscular elements arranged radially in the iris so that their action brings about an increase in the size of the pupil.

One of the chief functions served by the activities that are eventuated in the visual mechanism is the formation of images, and clear images of objects within a finite range of distances depend in a very essential way upon the accommodation of the lens. For objects at a distance of more than about 100 feet or so, no accommodation is required, but as the distance between the object and the eye becomes smaller, the lens needs to undergo a change so as to bring the portion of the total bundle of rays which emanates from the particular object into sharp focus. The lens is suspended from the edge of the ring of ciliary muscle by ligaments, and accommodation is reflexly controlled through changes in the muscle. As the muscle is brought into contraction in an increasing degree, depending on the proximity of the object up to the limit of the near-point, tension on the suspensory ligament is lessened more and more so as to allow the lens to increase its curvature chiefly at the anterior surface. This increases the power of the lens sufficiently to bring into sharp focus the rays which emanate from the proximate object.

Normally the visual image of an external object is a binocular compound, *i.e.*, the combination of the two images furnished by the two eyes. The fusion is effected in the central nervous system through a combination of the input of afferent impulses over the right and left optic nerves. The limit of fusion may be experimentally determined by maintaining fixation upon a stationary mark at a given distance while a similar mark is slowly moved away from the position of coincidence.

Another important visual function is that of perceiving objects in space, and the effectiveness

with which an organism makes adaptation to spatially disposed objects depends in a very large measure upon the efficiency of this function. It depends essentially upon image formation, and involves the mechanism for clear vision.

The relative distance of objects can be perceived monocularly in terms of interposition and differences in haze and size. It is in terms of variations in these criteria that the artist is able to produce the illusion of distance in a painting. Parallax also may serve as a monocular cue, *i.e.*, when the head is moved laterally, objects in the distance move in the same, those near at hand in the opposite direction. The degree of relative movement varies directly with the distance separating the objects and the lateral displacement of the head.

Binocular vision furnishes additional cues to depth perception. One of these is convergence, the two eyes converging increasingly as the proximity of an object increases. Another important factor is retinal disparity, which depends on the fact that each eye contributes a different view of space, owing to the distance separating them. The striking illusion of depth that is observed through the stereoscope is based upon this factor. The degree of disparity varies inversely with the square of the object-distance. Consequently, an important cue to depth inheres in the fused binocular image of the object in space.

The sensitivity of the photoreceptors to differences in the brightness of two apposed matt surfaces is measured by varying the energy which supplies one field until it becomes just perceptibly brighter (or darker) than the constant field. This determination has been made for surfaces emitting various homogeneous wave-lengths and for mixed light over a wide range of intensities (12 log units). As a function of log intensity, the reciprocal of the threshold is found in all cases to be a declining function, the rate of decline being rapid at first and becoming progressively less and less as the intensity of the stimulus is increased. The theory of neural availability is designed to indicate the nature of the mechanism involved in such intensity functions (Holway). This conception assumes that sensitivity depends on the number of neural elements available at the time that a discrimination is made. Sensitivity is assumed to be maximal when all elements in a given system are available and becomes pro-

gressively less and less as more and more elements in the functional mechanism are unavailable when the discrimination is being made. When stimulus-intensity is low, provided there has been no significant pre-exposure, sensitivity is high, *i.e.*, the threshold small, because practically all of the neural elements are available; however, when the intensity is high, or if a high pre-exposure has been used, sensitivity is lower and the threshold larger because the number of the available neural elements is greatly reduced. This view regarding the neurophysiology of intensity discrimination is consistent with intensity functions for various other receptors as well as for the photoreceptors.

Differences in brightness influence the reactions of the photoreceptors to flicker. If a circular field containing 180° black and 180° white is slowly rotated, it is perceived to flicker. As the rate of rotation is increased, the frequency at which flicker first becomes imperceptible is reached. The critical fusion frequency varies with the level of the illumination under which observations are made. At low illuminations, fusion may occur at a frequency as low as 10 or 15 r.p.m., but as the illumination is increased, fusion occurs at a higher r.p.m. and may reach 60 or 70 r.p.m. The curve showing the manner in which c.f.f. varies as a function of intensity exhibits a break, and is assumed to be based upon two integral curves, one representing the function of the rods, the other that of the cones.

When the circular field contains unequal amounts of white and black, the frequency at which fusion occurs is lower when black is the dominant component, and higher when white contributes more than 180°. These findings signify that the excitatory processes underlying flicker persist longer under conditions of low than under those of high illumination, *i.e.*, the underlying excitatory conditions persist longer when neural availability is great than when a smaller number of elements is available.

The sensitivity of the photoreceptors is found to increase throughout a protracted stay in the dark, increasing most rapidly at first, and then at a rate which is more and more attenuated as time progresses. When stimulations are restricted to the fovea, the total range of increase in sensitivity is less, and the curve indicating change in sensitivity is regular, however, when stimulations are made in the parafovea, the

great range of increase in sensitivity is much greater and the function obtained exhibits a break. The break is assumed to indicate the transition from cone to rod activity, and the greater range regarding increase in sensitivity depends upon the difference in the functional mechanism in the fovea where cones and nervous elements are individually connected and in the parafovea where the activities in a number of rods and/or cones collect into an individual nerve fiber. The latter mechanism allows a much smaller luminous source to produce the minimum number of impulses per unit time required for a cortical response.

The photoreceptors differentiate differences in color and in modes of appearance of color. Extensive investigations have been made in regard to the extent of color differentiation, and elaborate techniques have been developed in connection with the study of this problem. The monochromometer provides a suitable means for controlling wave-length, the physical correlate of hue. Visibility functions are obtained under rich well-controlled conditions and depict relative sensitivity as a function of wave length. Maximal sensitivity (the reciprocal of the smallest threshold) is found to occur at about 554 m μ when the illumination is high, but shifts toward a shorter wave length as the illumination is reduced, being maximal at 511 m μ under twilight conditions. The change in wave length at which maximal sensitivity occurs as a function of change in illumination is known as the *Durkinje phenomenon*.

The photoreceptors in the fovea are more sensitive to color than are those in the parafovea. The perimeter is utilized in testing differences in color discrimination in the photoreceptors in different parts of the retina. In a zone just outside of the fovea, the characteristics of color discrimination for a normal eye are comparable to those in subjects who are deficient in respect of color discrimination (protanopes, deuteranopes), while in the outermost parts of the retina, color discrimination is lost altogether. The zones determined in perimetry are not to be regarded as fixed but as functional, since they are found to vary with the size of the stimulus used, or with the intensity of the illumination.

Many suggestions have been made regarding the neural mechanism basic to color differentiation. In spite of zealous efforts on the part

of some of the ablest men in visual science, however, no theory has been definitely verified. The view of Young-Helmholtz has exerted the widest influence. This is based on the conception that there are three kinds of cones, or three kinds of activities, selective with respect to wave length. Later views are based upon similar assumptions, and some workers have proposed views involving a more detailed differentiation of activities in the retina and in the optic nerve. This is illustrated in the view of G. E. Müller. Müller states that color depends upon a psychophysical excitation, and that several processes intervene between the incidence of light upon the retina and the eventuation of the psychophysical excitation. Radiant energy acts first upon photosensitive substances in the retina, giving rise to sensitizing processes. Three sensitizing processes, selective with respect to wave length, are assumed to exist and depending upon differences in the composition of the incident light, they are brought into action in differing relative intensities. Each sensitizing process comprises a catalytic coupling, in which a primary substance is converted into an intermediate-product that, in turn, acts by catalysis to occasion the accumulation of an end-product. As soon as the latter phase of the photosensitive process reaches a critical amount, secondary excitations which are basic to chromatic effects begin to be initiated in the retina and in the optic nerve as well. The secondary chromatic excitations are different for each of the three (initial) photosensitive processes, and through the simultaneous action of the three initial photosensitive processes in different relative intensities the secondary (chromatic) excitations are eventuated in sufficient diversity to provide resultant excitations for the psychophysical excitations basic to all hues. The details of this specification are as follows. The first photosensitive process gives rise in the retina to conversions that are basic to red and yellow, the second one to conversions to yellow and green, and the third one to conversions involved in the eventuation of blue. Each of the secondary conversions in the retina is involved in producing three additional conversions in chemical substances located farther along in the optic tract: red giving rise to red, yellow and white; yellow to yellow, green and white; green to green, blue and black; and blue to blue, red and black. Thus, depending upon

variation in wave length composition, the two reversible conversions in the retina $R \geq G$, $Y \geq B$ and the three conversions in the optic tract $r \geq g$, $y \geq b$, $w \geq bk$ are brought into action in diverse combinations, directions and proportions so as to provide resulting chromatic excitations sufficiently diversified to furnish the psychophysical excitations for all nuances of color. When the eye is stimulated by mixed light in which no wave length is dominant, Müller assumes that the selective processes are aroused in the definite relative amounts in which, in consequence of inherent antagonistic relations, the chromatic effects are mutually set aside and only the $w-bk$ conversion responsible for achromatic sensation is effective. Müller devoted much of the later years of his long life to an exhaustive effort that was designed to show that his assumptions regarding the mechanism for color are consistent with an enormous literature. Further intensive work will be needed, however, if this conception is to be validated.

The acuity of the photoreceptors is measured in experiments in which the limit for distinguishing detail is determined. As a function of illumination, acuity as regards the discrimination of two small luminous points is found to increase slowly over a small range, then to increase more rapidly over an extensive range of intensities, and finally to progress very slowly over a final range.

Acuity to differences in depth is measured by various standard procedures. A fine mark, e.g., a line or dot, is adjusted with respect to the position of a similar stationary mark just above or beside it (vernier acuity); or so as to coincide as exactly as possible with the position of the stationary mark (coincident acuity). These determinations can be made either monocularly or binocularly. Stereoscopic acuity always depends on binocular observation, in which the smallest perceptible difference in the depth of two marks is determined. The measured difference is converted to angular units by using the distance separating the axes of the two eyes as base. An extensive literature concerning depth acuity indicates that under favorable conditions one or less than one second of arc can be distinguished. When visual acuity is determined as a function of range, it is found to increase with an increase in range.

Visual acuity is optimal for stimulations in

the fovea, and decreases rapidly as stimulations are made at parafoveal distances in any direction away from the fovea. It was long believed that the limit for acuity was determined by the diameter of the individual retinal element, however, evidence has tended to show that acuity under favorable conditions is too good to be explained on this basis. Evidence from comparative anatomy indicates that animals in which the internal nuclear layer of the retina has greater dimensions (width and thickness) have greater acuity (Detwiler), however, a detailed mechanism for acuity eventually is to be specified in terms of functional rather than structural characteristics of the visual mechanism.

PHONORECEPTORS

The ear-drum responds to air disturbances occasioned by vibrating bodies and transmits the alternating pressure-differences impressed upon the drum to the oval window. The receiving units for sound are collections of about 15,000 hair cells, which are distributed along the spiral membrane of the cochlea of the inner ear. About one-fifth of the hair cells—the inner hair cells—are arranged in a single row along the inner side of the arch of Corti. The larger number of outer hair cells is arranged in banks, three deep at the base, four deep in the middle, and five deep at the apical end of the cochlea. These sensory cells are connected through definite nervous tracts with the auditory center in the temporal cortex. The fibers of the cochlear branch of the eighth cranial nerve supply them and make connection with other tracts which converge upon the lateral lemniscus to reach the primary auditory center. Although the structural features of the phonoreceptors have been carefully described, the way in which they are activated is not clearly established in all details.

One view is the following. The cross fibers of the basilar membrane, upon which the spiral organ of Corti rests, respond sympathetically to the character of the disturbance being set up in the endolymph while the alternating pressure arriving from the sound source is being delivered through the system of membranes and ossicles of the middle ear. The longer cross fibers respond to the lower and the shorter fibers to the higher frequencies. Although data recently obtained through the technique of stimulation deafness seem to be fairly consistent

with this view, certain difficulties confront those who advocate the view that the hair cells are activated in this manner.

A different view is that the hair cells are activated through the impacts which are impressed upon their cilia by the overhanging tectorial membrane. This is a gelatinous structure which extends over the hair cells and is capable of responding differentially to changes in frequency and intensity of stimulation.

If resonance is the principle through which a local portion of the basilar membrane (or of the tectorial membrane) is activated when a pattern of disturbance of definite frequency is set up in the endolymph, this principle meets a limit at frequencies above 800–1,000 c.p.s. This is owing to the fact that the functional properties of the nerve do not allow it to follow every frequency above this limit. To circumvent this difficulty, it has been suggested that above this frequency, response to change in frequency depends upon the total volley of impulses arriving in the temporal cortex. Details regarding the nature of events in the cortex are still largely lacking. When more details are forthcoming, the mechanism for frequency differentiation may be found to be fundamentally central rather than peripheral for all frequencies.

The phonoreceptors are capable of responding to periodic vibrations embracing frequencies over a range of 16–16,000 c.p.s., although this range contracts somewhat, particularly at the upper extreme, as a function of increasing age. Threshold measurements made over the total range of audible frequencies reveal that sensitivity (the reciprocal of the threshold) is maximal in the range of 1,000–2,000 c.p.s., and decreases progressively and rapidly as the frequency of the test-stimulus departs more and more in either direction from the range of greatest sensitivity.

Differential sensitivity to a given frequency has been measured over a range of intensive units in terms of the increment in pressure at the ear that is required to occasion a just perceptible increase in loudness. When such measurements are made for a given frequency, *e.g.*, 800 c.p.s., over a wide range of intensities, a function is obtained which shows how differential sensitivity varies as the intensity of a given frequency is increased. The typical curve of this function reveals that sensitivity is great-

est initially, decreases as intensity is increased rapidly at first, and then at a continuously more and more attenuated rate of change. Curves obtained for other frequencies are similar in form, although the total range of intensities is somewhat reduced.

Immediately following exposure to a strong vibratory stimulation for a given period, sensitivity to the given frequency is reduced. The auditory mechanism has adapted to the stimulus. When sensitivity is measured at successive intervals of time immediately after cessation of a strong protracted stimulation, a curve indicating the recovery of sensitivity is obtained. The curve exhibits a typical course, in which recovery is more rapid at first, then more and more gradual until recovery is complete. After a stronger (or longer) pre-stimulation, the curve indicating return of sensitivity exhibits the same general form; however, insensitivity initially is still greater, and the initial rate of recovery and the total time required for recovery are greater.

The theory of neural availability was conceived to supplement the volley theory so as to account for these findings. The fact that sensitivity is greatest within the limits of 1,000–2,000 c.p.s. denotes that neural availability is greatest for this range of frequencies and becomes progressively less for frequencies as one ascends or descends in the frequency scale on either side. For any given frequency, sensitivity is greatest at low, and least at very high intensities because the number of available elements is greatest in the former and less and less as one proceeds upward in the scale of intensities. After a pre-stimulation, the number of available elements is reduced temporarily (Field and Brücke). Hence sensitivity is reduced. During recovery from pre-stimulation, normal sensitivity gradually returns because the number of available elements comes back to normal.

VESTIBULAR RECEPTORS

In the inner walls of the membranous labyrinth of the inner ear are collections of hair cells which are activated by gravitational, propulsive, and centrifugal forces induced in the endolymph during and immediately following many bodily movements. These are the maculae in the utricle and saccule, and the cristae of the semicircular canals. Afferent impulses from these receptive systems often influence the effer-

ent impulses so as to mediate important postural adjustments.

The fact that impulses from these receptors interact with centers governing specific kinds of behavior is indicated in various ways. Conspicuous among these are the nystagmic (ocular) movements which are protographed during and immediately following a period of rotation. A variety of these are distinguished—*e.g.*, jerky saccadic movements, lagging pursuit movements, and sudden compensatory movements. The input over the vestibular branch of the eighth nerve also interacts with the centers which involve the efferent output to the arm, giving rise to what is technically known as past-pointing.

The effects of excessive and sustained stimulation of this receptive mechanism, often encountered in modern modes of rapid transit, are well known, *e.g.*, seasickness, flying sickness. The fact that interaction occurs in varying degrees has been revealed in experiments which show that the after-effects of rapid rotation are greatly lessened if the eyes are kept closed.

VISCERAL RECEPTORS

Inlaid in the membranous linings and in the tissues of the alimentary, reproductive, circulatory and respiratory systems are various receptor cells which are responsive to chemical, mechanical and/or thermal stimuli. These visceral receptors include free nerve-endings and encapsulated terminals which occur singly or in small collections, although they are differentiated functionally to respond to different kinds of stimuli, so as to meet a variety of needs.

In the upper alimentary tract are collections of receptors which serve to indicate the suitability of the materials that are to be taken into the tract to serve the general nutritive functions. These are the gustatory and olfactory receptors. They are sometimes designated chemoreceptors, because the stimuli enter into chemical action with substances residing in the terminals of the receptor in initiating the characteristic receptor action.

Taste cells are elongated structures that are assembled in the form of a bud. Taste buds appear in chains or singly, being scattered somewhat over the tongue and chiefly in the crevices along the sides and back. They appear also in the membranous walls of other struc-

tures in the posterior pharynx. These receptive cells are supplied by fibers from branches of the fifth, seventh and ninth cranial nerves. The activities initiated in the taste buds are conveyed through these nerves to the central nervous system.

Among the investigations made to determine the nature of function in these receptors are those concerning reaction-time. This index-response is found to vary inversely with the pressure, the concentration, and the taste of any given gustatory solution, as well as with the size of the area exposed to the substance. These findings denote that gustatory reaction-time becomes shorter as more and more neural elements are involved in the reaction. Measurements of differential sensitivity to a given gustatory solution show that sensitivity is optimal at low intensities, and decreases progressively, at first more rapidly and then more and more slowly, as the intensity of the stimulus is increased. This result also is consistent with the conception of neural availability. Investigations have not yet revealed whether a taste bud contains several different kinds of cells or whether a given cell is stocked with several different kinds of substance which give rise to different kinds of activity in the receptive system to account for the primary gustatory qualities (sweet, salt, sour, bitter).

The olfactory receptor comprises a collection of nerve terminals in the upper nasal cavity. These cells are activated through chemical action when particles of volatile substances borne in the air are taken into the nostrils and become dissolved in the fluid which overspreads them. The activities which are the sequel to this chemical activity are propagated over the first cranial nerve to the olfactory center in the hippocampus.

Although the olfactory system gives rise to a large number of different qualities, evidence has not yet been brought forward to indicate whether different kinds of olfactory cells are basic to qualitative differences or whether the cell is stocked with a variety of chemical substances through which different modes of action are eventuated in the given cell.

However, evidence regarding the lawful relations existing between the stimulus and the receptor has been brought forward. The rate of adaptation to a given olfactory substance is a linear function of the amount of the stimulus

presented to the receptor. Sensitivity is greater for dirhynch than for monorhynch stimulation. Differential sensitivity is maximal at low intensities and becomes less and less, at first more rapidly and then more slowly, as the intensity of the stimulus is increased. These findings are consistent with expectation in terms of the conception of neural availability.

The receptors in the lower alimentary tract are largely protective in function, responding to variegated thermal and mechanical stimulations. Local parts of the lining of the reproductive system contain the encapsulated terminals of afferent nerves which respond to light and thermal pressure so as to build up the spastic reproductive reflexes. The terminals of afferent nerves in the respiratory and circulatory systems are responsive also to extreme modes of stimulation.

SOMESTHETIC RECEPTORS

The terminals of afferent nerves are distributed at different levels of the integument investing the tissues of the body. These receptors are activated when local (pressure, thermal, chemical) changes are occasioned. A large number of receptor-structures have been described, e.g., free nerve endings, hair roots, organs of Krause, Golgi-Mazzoni, Ruffini, Merkel's discs, corpuscles of Meissner, Pacini, Herbst, but a specific receptive function for all of these various structures has not yet been established. The afferent processes attending diverse stimulations on the skin, however, are propagated over well differentiated pathways to the somesthetic center in the parietal lobe of the brain.

Persistent efforts have been made to determine the structures specifically involved in the evocation of each of the basic cutaneous qualities—pressure, pain, warmth, and cold. To date, however, these efforts have not been successful. The method of electrical recording has revealed a definite difference in the nature of activities in afferent nerves when typical stimulations for pressure and for pain are made; i.e., long and narrow spikes for pressure, and short and wide ones for pain. The prevailing view is that a different receptor is to be specified for each of these qualities.

Surveys of the extensive body of experimental literature have frequently been made, the most thoroughgoing recent one being that of von Skramlik. The studies of chief concern are those

dealing with the sensitivity and acuity of these receptors.

Two distinct methods have been utilized to study the acuity of the skin, the error localization and the limen of duality. For any given surface of the body, the former is usually found to be about one-third the size of the latter. This is owing to the fact that the error of localization is based on trials in which two successive stimulations are made so close as to be indistinguishable, whereas the two-point limen includes simultaneous stimulations by two points separated widely enough so as to be perceived as two in one-half of the cases and separated so as to be just not distinguishable as two in the other half of the cases. The fact that actual acuity, as measured by either of these methods, is many times greater in certain regions (lips, finger tips) than in others (thigh, back) depends on differences in the density and perhaps the character of the receptors per unit area.

The sensitivity of the skin has been determined chiefly with respect to changes in pressure and temperature. When precautions are taken to reduce extramodal stimulation to a minimum, the sensitivity functions obtained in both of these cases show the same general trend; i.e., differential sensitivity (= sensitivity to difference) is greatest at low intensities, decreases rapidly at first, then more and more slowly as the intensity of the pressure or temperature is increased. This is consistent with the manner in which neural elements may be presumed to enter with these determinations. When the intensity is low, more neural elements are available, and sensitivity is greater; as the intensity becomes greater, the number of elements available for the discrimination of an increase in intensity decreases, and the sensitivity becomes poorer.

THE PROPRIOCEPTORS

The proprioceptors comprise diverse structures scattered throughout many bodily tissues that respond to tensile stimulation. Chief among these are the muscle spindles, tendons of Golgi, and Pacini corpuscles. The muscle spindles are distributed here and there among other elongated muscular cells which are supplied by efferent nerves. Each muscle spindle is a separate unit, and comprises one or more cylindrical cells which are considerably smaller than the associated muscular cells which im-

press tension upon them during a contraction. Imbedded in the tendons and in the fascia adjacent to the tendons are structures known as tendons of Golgi which also are receptive to the tensile stimulation delivered when the muscles to which they are attached contract. Other encapsulated endings, chiefly Pacini corpuscles inlaid in the membranous linings of the joints, are activated by the deformation occasioned *e.g.*, when a ball moves in its socket. This system of receptors serves to indicate the nature of local changes in position in various parts of the body.

The input of afferent impulses from the proprioceptors is conducted to centers at various levels of the nervous system—first to the spinal cord, next over the proprioceptive paths in the posterior horn to nuclei in the medulla, then either over the inferior peduncle (restiform body) to the cerebellum or over the lateral lemniscus to the thalamus, and finally to the somesthetic cortex in the parietal lobe of the cerebrum.

Various functional mechanisms are provided for in the proprioceptive system, with the afferent input being integrated at different levels in the nervous system. The postural reflexes which are differently utilized in different forms of locomotion depend essentially on integration in subcortical centers. The motor skills which involve the use of tools, instruments, and machines, depend, particularly initially, upon integration at the cortical level. The general importance of the functions served by the proprioceptors has served to give great impetus to the study of functional characteristics of proprioceptive mechanisms. Various techniques have been conceived and developed.

The way in which impulses from proprioceptors vary, when tensile stimulation varies, has been determined via the technique of electrical recording. The frequency of impulse discharge from muscle spindles is found to increase in direct proportion to the intensity of mechanical or electrical stimulation. The discharge from Pacini corpuscles has been shown to exhibit a similar relation to changes in intensity of stimulation.

The sensitivity of the proprioceptors has been much studied through the technique of weight discrimination. For a particular proprioceptive system, sensitivity is greatest when intensity is low and decreases at first more rapidly and

continuously at a more attenuated rate as the intensity of stimulation is increased over a wide range of intensities. This is owing to the fact that the discrimination is based on a smaller number of neural elements as the intensity of the stimulus is increased. By the same token, sensitivity is found to be greater for bimanual than for unimanual comparisons, and is greater for a more extensive system of muscles than for a more restricted system, *i.e.*, when weights are lifted with the shoulder as fulcrum sensitivity is greater than when the elbow is fulcrum; sensitivity is least when the wrist is fulcrum.

The sensitivity of a given proprioceptive system is impaired immediately following pre-exposure to a weight. When the pre-exposure involves a heavy weight, the degree of reduction in sensitivity is greater than for pre-exposure to a lighter weight. Likewise a longer pre-exposure to a weight serves to reduce sensitivity to a greater extent than a shorter pre-exposure to the same weight. The reduction in sensitivity as a function of pre-exposure time is correlated with progressive changes in the functional mechanism which have been revealed by other techniques, *i.e.*, the progressive increase in the refractory period during a sustained stimulation and the accumulation of organic by-products of nerve activity, *e.g.*, increase in carbon dioxide, heat production, etc. These changes in the system signify that the number of neural elements available for a discrimination decreases progressively as a function of time during a moderately strong pre-exposure and at a rate which varies directly with the amount of the pre-exposure stimulation.

The way in which dynamic changes are induced in proprioceptive systems during a sustained stimulation provides an explanation of various inconsistencies which often have been reported in the comparison of weights. The heavier of two weights is judged to be the lighter in bimanual comparisons just after a protracted pre-stimulation has been made on the side which is to be used to lift the heavier weight. Owing to the temporary increase in the refractory period on the pre-stimulated side, fewer impulses are able to be propagated to the somesthetic cortex over the nerves from that side than over those from the other (unfatigued) side. The observation that a light

weight seems lighter than usual (so called negative weight) just after a period in which heavy weights have been handled denotes that fewer impulses than usual are propagated to the cortex during the time that the after effects of the previous intensive stimulation are still operating in the proprioceptive system.

THE EFFECTORS

The Response Unit. A motor response to external stimulation involves an overt expression of activity in the effectors—the muscles and the glands. The activity in the muscles is the consummation of a train of neuromuscular events. The activity gradient that is occasioned in a primary sensory center during an external stimulation gives rise to locally differentiated trains of impulses which pass to the motor cortex, down over the motor tracts, and out over the efferent nerves to the muscles. The way in which trains of neural activities engage the muscles in the kind of activity that is a suitable response to a momentary situation is to be understood only through a detailed knowledge of the functional events involved in eventuating organic movement.

The nature of the response eventuated depends in part upon the kind of muscle brought into action. Two kinds of muscle—striate and smooth—are usually distinguished, in addition to the special muscle found in the heart, the organ designed to serve the vital function of perfusing blood through the tissues of the body. In general, striate muscles include the muscles in which fibers are arranged in bundles, invested by fascia, and attached to the skeletal framework of the body. These bundles vary in size, depending upon the parts to which they are attached and the nature of the work which they are designed to perform. Striate muscles receive their nerve supply from the cerebro-spinal system and subserve numerous voluntary acts, e.g., running, walking, jumping, climbing, throwing. Two subdivisions of striate muscle—light and dark—are distinguished on the basis of their appearance. Dark striate muscles contain myoglobin, i.e., corpuscles that resemble the hemoglobin of the blood and are believed to subserve activities that often need to be long sustained. Light striate muscle is a more specialized variety of striate muscle and is more exclusively involved in sudden responses.

In smooth muscle the individual fibers are

not arranged in bundles so as to provide for strength and promptness of action. Instead, they are assembled into the relatively thin muscular layers that appear, e.g., in the walls of blood vessels and of the alimentary tract so as to sustain more attenuated (tonic) modes of muscular action. The efferent nerves which supply these muscles emerge from the autonomic chain of ganglia. Important involuntary functions, e.g., peristalsis in the alimentary system, and vasoconstriction and vasodilation in the circulatory system, are subserved by activities eventuated in smooth muscles through activities in the autonomic system.

A conception of the way in which muscular response is eventuated is best envisaged through a detailed study of the characteristics of individual muscular elements. In striate muscle, there are cylindrical cells with tapered ends, varying from 1 to 40 mm. in length, and from 10 to 100 microns in diameter. Many of the elongated cells are compound, each being invested in a thin membranous wall (sarcolemma). Threadlike fibers (myofibrils) run lengthwise in the cell and are surrounded by a fluid (sarcoplasma). The fibrils exhibit alternate light and dark bands, indicating a complex composition. The individual fibers in smooth muscle are similar in form to those in striate muscle, but the dimensions are somewhat reduced.

Each muscle cell has its own circulatory and lymph systems, through which supplies are received and wastes eliminated. These cells are stocked with various organic substances: e.g., myosin and myogen (proteins), glycogen (carbohydrate), phosphocreatine (nitrogenous material). The way in which activities in individual cells bring about a contraction is not fully to be elucidated, however, certain temporal relations regarding the changes which occur among the materials residing in the muscle cell during activity have been specified.

The fibril of an efferent nerve pierces the sarcolemma which invests the muscle cell, and ends either in a motor end-plate, which has dimensions of 40 to 60 microns, or in a grape-like terminal. The neurilemma of the nerve is continuous with the sarcolemma of the muscle cell, however, the myelin sheath is lost just before the cell is reached. Through this connection the nervous activities known to be attended by definite chemical changes (*vide*

supra) may be presumed in some as yet undisclosed way to be antecedent to and continuous with chemical relations within the cell.

In the resting state, a chemical balance is automatically maintained in the muscle cell by the alimentary and circulatory systems. This balance is altered, however, during nervous and muscular activity. Specific changes have been shown to take place. Phosphocreatine is broken down into phosphoric acid and creatine. This is a reversible process, *i.e.*, the phosphocreatine is subsequently resynthesized from its decomposition products partly during an anaerobic and completed during an aerobic phase of the period of relaxation. Somewhat later the glycogen which is stored in the cells begins to be converted into lactic acid, and the energy produced during this conversion is believed to be essential to bringing the sarcolemma into the action which effects a shortening of the muscle cell. This conversion also is reversible, a large portion of the lactic acid being resynthesized into glycogen during relaxation. Oxygen, supplied through the respiratory and circulatory systems, is also utilized in this conversion. The chemical economy of the muscle cell needs to be elucidated in greater detail if a complete specification of the intricate dynamic relations which occur in muscle cells during activity is to be provided.

Interspersed among the cylindrical muscle cells which are supplied by efferent fibers are the muscle spindles supplied by afferent fibers. These comprise small bundles of 3 to 10 smaller muscle fibers (1 to 5 mm. in length) surrounded by several layers of connective tissue. When activities passing over the efferent paths bring about a muscular contraction, these smaller muscle cells (proprioceptors) are compressed, giving rise to an input of impulses over their afferent nerves. Through differences in the intensity and spatial distribution of these impulses, the nature of the ensuing output of impulses over the efferents is influenced so as to suit the varying needs of a momentary situation. In this way the nature of the neural output to the muscles is governed by the input over the afferent nerves from the muscles, and a sequence of muscular changes suited to the needs of a complex situation is eventuated.

Behavior patterns are manifestations of activities on the part of a population of muscle cells involving them in diverse temporal, spatial and

intensive relations. In simpler acts, the activities are restricted to a small system of muscles, while in complex acts the activities include muscle cells in widely scattered parts of the body. Skills that involve the use of instruments, tools, etc., depend upon learning to bring a population of effectors into action in suitable spatial, temporal and intensive relations. Through the characteristics of the action of individual cells and the way they can be brought into action in diverse relations, the diverse behavior patterns of the individual are provided for.

The central nervous system serves to coordinate activities in muscles in widely scattered parts of the body, *e.g.*, in such a complex act as maintaining balance in skating. The nature of the input over various afferent systems is brought to bear differentially upon diverse motor ganglia so that the muscles concerned with moving different parts of the body are brought into synchronized action. Momentary changes in the character of the afferent input are thus able to influence the character (intensive, spatial, temporal) of the pattern of impulses being distributed over the efferents.

The efferent nerves which emerge from the autonomic chain also supply a large number of glands. Some of these are concerned essentially with nutritive functions and thus are involved only indirectly in muscular action. They at least participate in the maintenance of various kinds of chemical balance among the materials which are stored up in the muscle cell. Other glands, *e.g.*, the adrenals, are known to play an essential supporting role in the activities of smooth muscle, *e.g.*, in vasoconstriction. The diverse ways in which glandular secretions influence various behavior characteristics are just being brought into focus, and painstaking efforts will have to be expended before their role is properly evaluated.

RELIGION, THE PSYCHOLOGY OF.

—A number of texts have been published under the title of *Psychology of Religion*; but most of these books treat only a limited range of topics, confining themselves usually to the topics which today are classed under the heading of "Religious Pathology." Other books indicate more definitely the topics with which they deal, by titles such as: "Psychology of Religious Mysti-

cism"; "Psychology of Religious Belief," etc.; and journal articles have usually indicated the limited topics discussed by their authors.

The first book to be published under the title of *Psychology of Religion* appears to have been the one by Starbuck, (1) although other books which would have merited the name more logically had appeared under other titles. The second book which might have been called by this title, was James' *Varieties of Religious Experience* (2), although this book also dealt mainly with pathological topics, James' book still continues to be important, while Starbuck's has disappeared from most bibliographies.

So far no text has appeared which could serve as a text-book for a course in which religion is to be treated from the psychological point of view. What students want is information about religion which will enable them to evaluate the role which religion can play in civilized life; the usefulness for society and for the person. Such evaluation is possible for an author or an instructor who is well grounded in the principles and methods of group psychology, and of personal psychology (so-called "general psychology"), and who also is well oriented in the field of religion, and understands the comparative and genetic methods as applied in that field and in the field of group psychology.

Two difficulties are encountered in the attempt to instruct college students in the psychology of religion. The first is the lack of background, not only in group psychology, but also in general psychology, which I prefer to call "personal psychology." Apparently, since the era of "mental testing," courses in elementary psychology have failed to give students a grounding in scientific psychology, and ignorance of the principles and methods of group psychology is as evident.

The second difficulty arises from the complete ignorance of the broader aspects of the subject on the part of students of religion. Most students approach the study in the light of a particular religion such as Judaism, or of a particular Christian sect such as Methodism. Those who are anti-religious are as ignorant as are the pious; they are opposed merely to religious tenets and practices with which their limited personal experiences have familiarized them. These college students represent, of course, a cross-section of the general public, among whom ignorance of religion is as great. A useful text would be one which

should convey to the student, and to the general reader, basic information about the religions of the world, or at least about the so-called "great religions." Lacking such a text, the instructor in a college course has to consume time in giving the necessary information.

Any study of religion is really in the field of psychology, whether or not the one making the study is a psychologist. Religion is a feature of conscious life, and psychology is the science of conscious processes and their conditions. Religion, in its long course of development, has been produced by man's desires and purposes and the objectives he has consciously maintained. Hence the examination of these conscious processes is an essential task for the "Psychology of Religion." These determining factors, of course, must be examined with reference to the conditions under which they occurred and operated, just as personal psychology must be studied in relation to the organism and its environment.

The important conditions under which human desires and purposes have produced and further modified religion cover a wide range, including all factors which may be called "cultural." Geographical and linguistic conditions have been influential: war has had its impact, but the most important factors have been those which can be called economic in the broad meaning of the term "economic." Among the important economic conditions, the praxes of agriculture, horticulture and animal husbandry are admitted by all scholars to have been of major influence, regardless of the theoretical conclusions the scholars have drawn. Commercial and industrial conditions, and the praxes of hunting and fishing in the earlier periods, also need consideration.

That inventions made in the service of economic improvement have had influences on religion is evident from the adoption of the hammer, the axe, the spear, the sword, the ladder, and the wheel as religious symbols. The reasons why other inventions such as the plough and the mill for grinding grain did not become religious symbols must be sought; the reasons are easily conjectured, but no one seems to have investigated the problem.

It may be admitted that pathological topics such as conversion, repentance, etc., are involved in the full study of the psychology of religion, but the normal features of religion

are far more important. Psychologists are more interested in preventing the pathological conscious processes than they are in them as indications of the nature of religion; they are studied mainly in the interest of religious prophylaxis.

In almost all subjects of instruction today, it is admitted that the facts of the present can be understood only through the results of application of the comparative and genetic methods. This is as true of the study of religion as it is of zoology or linguistics. To evaluate religion one must understand religion, and to understand religion one must know a great deal about its evolution. Unless one understands the roles which religion has played in the cultures of the past, one cannot understand the role it plays at present; still less can one evaluate the role it may play in the civilization of the future. Comparison of present-day religions is also helpful.

For collegiate instruction and for the general reader, the problem raised by these requirements is difficult indeed. There are a few scholarly histories of religion, among them two works by Moore (3, 4), and two by Hopkins (5, 6); but these books are not easy reading for the average person. As for more elementary texts on religion from the comparative point of view, few are satisfactory. Aside from biased points of view of the authors, they depend on assumptions which have been discarded by scholars, and some of the authors appear not to understand the materials they present, and so miss the vital points of the religions which they discuss.

Comparison of the religions of unlettered peoples with those of civilized and semicivilized groups is difficult. The sources are widely scattered in the writings of explorers, anthropologists and missionaries, and the collection, interpretation and organization of the materials is a labor of scholarship of which few persons are capable. Unfortunately, the reports on the religions of savages (the unlettered peoples whom anthropologists misleadingly call "primitive") present the savage concepts in terms of civilized concepts, which, in the majority of cases, do not represent the savage ones with any degree of accuracy. A typical procedure is to render a variety of savage terms, which the savages distinguish from one another by the word "soul."

A similar difficulty is encountered when Greek religion, or Egyptian religion, is studied

in translations. We might excuse translators who render nine different Greek terms for human appurtenances by the four "vagrant" English words, *soul*, *heart*, *mind*, *spirit*, using these four words interchangeably. These Greek words changed their meanings progressively from Homer to Plato, and the translators pay little attention to the changes. Budge, on the other hand, is less excusable, for he distinguished the meanings of the various Egyptian words for human appurtenances such as *Ka*, *Ba*, *Khu*, etc., but in his translations he renders them all as "soul"! The concepts of savages, however, have not changed, except under the influence of missionaries, for savage cultures have been static for centuries. If reporters and translators would transliterate terms in the original languages into a modern language and avoid translating them, confusion would be reduced to a minimum.

Books have been written on so-called "primitive" religion and on the religions of particular savage groups, but the authors of these books appear to be insufficiently oriented in the methods and principles of comparative religion. It is clear that one who writes on religions of unlettered peoples should, first of all, become acquainted with the development of the religions of civilization.

Perhaps the best source of materials on the religions of unlettered peoples is Frazer's *Golden Bough* (7). Frazer, who well knew the difficulties to be encountered in using the reports of ethnologists, explorers and missionaries, was more discriminating in his compilations than are most compilers. His theories, which he changed progressively as his work continued, are unimportant.

Among religions of semicivilized peoples, the numerous religions of India offer a problem for comparative religion which is somewhat different from the problem of savage religions. Most of the writers on Hindu religions seem naively to have accepted the Hindu traditions which ascribe great antiquity to their sacred writings. Hindu religions, however, except for those of modern sects which have been influenced by Christianity, seem little further advanced than were Greek and Levantine religions at the time of Homer (800 to 1000 B.C.). The Vedas were not actually composed until the Christian era, and Greek influence on Hindu concepts is evident. The soundest book avail-

able on Hindu religions is still that of Hopkins (8), which was published fifty years ago.

It is fortunate that for the understanding of the religions of civilized peoples a full comparative study is not necessary. Comparison of civilized religions with savage and semicivilized religions is important for the understanding of the changes which Christianity has suffered in savage areas into which it has been introduced; but in the face of the difficulties above set forth, study of the development of civilized religions from its origins in the Mediterranean, Levantine, and Celtic religions can suffice. We cannot trace civilized religion back to its really primitive stage, but we can trace it back far enough to infer to the roots of religion in the areas where civilization passed its infantile stages.

In so far as materials on Mediterranean, Levantine, and Celtic cultures and religions are available, they have been collected, analyzed and organized by scholars, and no further work remains to be done, except critical evaluation of interpretations and conclusions of the scholars, which are not always sound.

Among the compendiums available are Cook's *Zeus* (9), embodying the work of a lifetime, and Reinach's collection of essays (10). These works are not for the average reader but for the researcher. Cook's volumes are badly organized, with material distributed through text, footnotes and appendices; and Cook's conclusions are sometimes opposed by the material he presents. The postulates of "Nature-religion" are sources of some of Cook's conclusions, but his volumes are the last words in collection of data and documentation thereof. Reinach's volumes have not been translated from the French, but his French is not difficult. The volumes are revealing for some features of Judaism, and are the best available sources for Celtic religion, while his analyses of some points in Mediterranean and Levantine religions are not matched by those of Cook. Reinach depended too much on the postulates of animism and totemism, but these factors are easily eliminated by a careful reader. The materials collected so competently by Cook and Reinach can be supplemented from references 12 and 13, and the researcher will seldom need to revert to the original sources.

For the genetics of Judaism there is an abundance of material available, some of which is discriminately treated in Reinach's essays. Some

scholars, unfortunately, have obscured the problem by presenting their materials so that intelligent readers with some orientation in comparative religion and mythology can grasp the points, while veiling their conclusions in such a way as to avoid offending the orthodox groups who had supplied funds for the authors' work. Sayce (11) is an illustration of a scholar who presented conclusions which he well knew were deceptive.

On the development of Islam (Mohammedanism), material is not so abundant or so available. Books for student use give Islam scanty treatment, which might be justified on the ground that Islam is a synthetic religion in which features of Judaism and Christianity were grafted on ancient Arabian religion. Information can be obtained from the appropriate topics in the *Encyclopedia Britannica*, Eleventh Edition (12), and reprints thereof, although the rarer Ninth Edition is even better. Editions later than the fourteenth are not recommended, since the articles were written by hack-writers, while the articles in the early editions were written by scholars of eminence. The *Encyclopedia of Religion and Ethics* (13), edited by James Hastings, is also highly useful, not only for information on Islam, but also on most other topics in the field of religion. On the religions of the Southern Levant, from which early Arabian religion and Judaism evolved, the book by W. Robertson Smith (14) is still useful.

In studying the evolution of civilized religion, in addition to the cultural conditions in which it developed, the branching of religions into sects, between which there is often a greater divergence than between cults which are said to be different "religions," needs consideration. Two sects which have developed from the same stalk are still called by the name of the original parent stalk. The difference between sects and religions, in short, being one of history, not of doctrines. On the other hand, the assimilation by one "religion" of features of other "religions" must be considered. As I have said above, one cannot understand religion unless one understands its process of development.

The psychology of religion is primarily a topic in the field of group psychology, with personal psychology secondary in importance. This is evident from the principle now accepted by scholars, that faith develops from

ritual, not ritual from faith. This principle did not gain immediate acceptance when Robertson Smith proposed it, but is now considered sound. That the branching of a religion into sects is a group matter is obvious. That a religion cannot be imposed on a people unless the "new" religion assimilates ritual features and festivals of the "old" religion is commonly admitted; and this, of course, is a group matter.

Before more books are written on the psychology of religion, there should be much work done by psychologists who understand the genetic and comparative methods, especially as these methods are applied in group psychology—psychologists who are able to analyze the psychological factors which have determined the evolution of civilized religion from the earliest point in the history of civilization to which it can be traced back. Only when this has been accomplished can we evaluate the role religion can play in the future of civilization and evaluate the significance of the pathological features of religion.

RELIGION AND PSYCHIATRY (An Approach to European Psychology of Religion).—What may be termed the last skirmish in Europe's long conflict between science and religion took place hardly a generation ago. This time the argument was between the new twentieth-century scientific psychotherapy and *Seelsorge*, as religious psychotherapy was called in German-speaking countries.

Sigmund Freud of the psychoanalytic wing of scientific psychotherapy brought into the open this controversy with an attack on religious psychotherapy and the supernaturalism with which it was so intimately bound. Branding religion as a species of superstition, yet attributing some therapeutic value to it, Freud attempted in *Die Zukunft einer illusion* (1927) to explain away religion as a grand compulsion-neurosis which gave a false sense of security by simply masking the minor neuroses of life. He saw this neurosis originating in the infantile fear of and resignation to the real father who frustrated the incestuous sexual yearnings of the little boy for his mother. In adulthood this infantile fear of and resignation to the father, now surviving in the super-ego of the adult, are reactivated in the presence of libidinous stirrings of any sort. This conception of religion as a compulsion-neurosis had been one of long standing with Freud, who first broached it as far back as 1907 in *Zwangshandlungen und Religionsübungen* and subsequently enlarged upon it in *Totem und Tabu* (1912-13). In the work of 1927 it is maintained that in the light of the marvellous advances of scientific psychotherapy, religious psychotherapy as handmaid of supernaturalism has become definitely outmoded and should go the way of all pre-scientific illusions.

In answer to this attack protagonists of religious psychotherapy sought to defend the non-illusory character and genuine psychotherapeutic value of religion. They admitted the need of a knowledge of scientific psychotherapy on the part of the modern *Seelsorger*, and they sought to enlighten their opponent with the generic in the nature of religion and *Seelsorge*.

The theologically trained religious psychologist and leading exponent of the Würzburg-inspired experimental approach to the psychology of religion, Werner Gruhn, in his *Seelsorge im Lichte der gegenwärtigen Psychologie* (1927) defined *Seelsorge* as care of the soul.

By tradition, *Seelsorge*, variously styled pastoral theology, practical theology, Christotherapy, pneumatic therapy, spiritual guidance, had signified care of the soul in the sense of spiritual consolation at the hands of clergymen officially commissioned by the church. This psychotherapy is religious in the sense that the therapeutic effects are understood by the distressed soul to flow from God, or the Savior, or the church, with the clergyman merely serving as mediator. This soul-care can be by means of physical assistance, counsel, instruction, encouragement, chastisement, interest in, understanding, confidence in, sympathy, forbearance, fighting with, living with, bearing testimony of salvation through Christ, interceding prayer. The keynote of it, according to Gruehn, is *active love*, charity, helping as we have been helped.

Gruehn would broaden the concept of *Seelsorge* beyond its traditional meaning. He would, in the first place, have *Seelsorge* retain its pneumatic or spiritual character while absorbing much of value in the way of the causation and therapy of personality disturbance from scientific psychotherapy. Too often the priceless ingredient of *Seelsorge*—namely, *charitas*—is just that which is missing in scientific psychotherapy. Without this ingredient scientific psychotherapy is but “sounding brass and tinkling cymbal.”

In the second place, Gruehn would no longer restrict the practice of *Seelsorge* to clergymen. “*Seelsorge* would embrace not only preaching, confirmation instruction, not only liturgy and mission teaching, but every assistance which one person renders another, be he physician who helps his patient, or mother who helps her child, or friend who helps friend—every assistance which is determined by deeper motives carries already spiritual guidance character in itself.” “*Seelsorge* is not merely an affair of the pastor.”

In the third place, Gruehn believes that *Seelsorge*, as he more broadly conceives it, will of necessity retain its pneumatic (i.e., spiritual) character, but that in a truly deeper sense. The God from whom all blessings flow becomes a God of Love. The disillusioned soul is led to an abiding faith in a transcendent power, to a new, relatively fruitful inner life, just through the unselfish love, the unshakable faith, hope and charity exemplified in the person of the *Seelsorger* who deals honorably with his neigh-

bor. It is in reality this new access to God that brings peace to a troubled soul. God is no longer the God of childhood fancies, but rather a living reality in the person of a true friend sorely needed. *Seelsorge* must have something more to offer the soul in distress than a better Hereafter, than “a draft on the stars.” The task of the new *Seelsorger* is that of saving souls for this world.

In the fourth place, Gruehn, in his enlargement of the meaning of *Seelsorge* to embrace all there is of value in scientific psychotherapy, sees it incumbent on the *Seelsorger* to provide himself with all the knowledge possible of general psychology, religious psychology, scientific psychotherapy, pedagogy, etc. “Who should know the human soul more than he who would help it?” What is *Seelsorge* ultimately but “psychology applied under pneumatic viewpoints.”

Very much the same point of view as that of Werner Gruehn's is set forth by Marcus Gregory in his *Psychotherapy, Scientific and Religious* (London, 1939). While lay (i.e., scientific) psychotherapy and spiritual or pneumatic psychotherapy have evolved in the past somewhat independently, there is much that is common to both, much that each can well borrow from the other. Out of this pooling of the best from each other, Gregory would see spring the *Seelsorger* of the future, who is at once God and man. “The power of the ideal healer,” according to Gregory, is dependent upon identification with the patient, and that, ultimately, is based upon the greatest gift of all—that of love. The healer who seeks apotheosis will be hated by the “gods,” but the love of the ideal healer is sure to be met with adoration.”

An actual step in the direction of enlarging the scope of *Seelsorge* in such wise as to absorb lay psychotherapy and to provide the *Seelsorger* with all possible scientific knowledge pertinent to the etiology and therapy of personal disorganization had already been taken by a branch of the Verein katholischer Akademiker in instituting three-day meetings at Kevalaer in March, 1925, March, 1926, and March, 1927. At these conferences, papers were presented by physicians, theologians and pedagogues which centered around the theme, “Border Questions Between Religious and Scientific Therapeutics.” These lectures and discussions were subsequently edited and published in three volumes by

Wilhelm Bergmann under the title *Religion und Seelenleiden* (1926, 1927 and 1928). Constitutional, physiogenic and sociogenic factors in personality disturbance are set forth in a surprisingly candid fashion, and free discussion of both psychoanalytic and individual psychology methods of diagnosing and treating functional disorders is carried on in a similarly frank manner, considering that the entire program was under the auspices of the church. Most interesting of all is the frank admission of errors on the part of ecclesiastical therapists. Religious instruction is admitted as erring in imparting a naive anthropomorphic conception of God. For thousands, God remains throughout life a heartless, unsympathetic tyrant, a father more wrathful, capricious and unreasonable than their own father. Even somewhat more wholesome would be an anthropomorphic notion of God as Friend or as Mother. The notion of God as wrathful, and the dread of judgment day are conducive to anxiety and morbid conscience. Belief in the devil also promotes anxiety and at times epidemics of witchcraft. Overzealousness on the part of religious instructors and intolerance for less than perfect piety in their pupils make for morbid complexes of suspiciousness and overscrupulosity, for joylessness, lack of courage, melancholy. Encouragement to mysticism in those predisposed to hysteria is conducive to a dreamy religiosity and the latter's morbid effects; namely, hopes without prospect, morbid wishes and yearnings, autism, a fantastical living in fairyland. While the Catholic confession has at bottom psychohygienic and psychotherapeutic value as a catharsis, much of its success depends on the confessor-father, who can err from lack of scientific preparation for his role as *Seelsorger*, from lack of *Einfühlung* into the soul of the confessee, from too erotic attachment to his confessee, from fostering a morbid conscience.

Prinzhorn, Schultze-Maizier, Jaspers and Jung came with integrative solutions of the controversy which stressed the religiosity of sincere psychiatric activity and the psychiatric nature of religiosity.

Hans Prinzhorn in his *Psychotherapie* (1929) sought a common footing not only for religious psychotherapy and scientific psychotherapy but also for the various interirrevalling schools of scientific psychotherapy. As a philosopher of psychotherapy he sees the cause of causes of

neuroticism in an exaggerated egocentrism and the principle of principles of psychotherapy in a reduction of this egocentrism by any of several means—in fact, by any means which will take the neurotic's mind off of himself and direct it to something larger than himself, whether it be a task, the writing out of his dreams, the psychotherapist himself, a friend, society, a teacher, a priest, or God. Selfishness is abnormal. Man is normally a social animal. Ego deflation must be achieved in an as unobtrusive a manner as possible or else the neurotic will be driven back into an even more morbid egotism. Everything in this matter depends on the personality of the psychotherapist. Be he teacher, priest, physician, pastor or friend, the psychotherapist must possess, besides a comprehensive knowledge of human personality, above all else a sympathetic human understanding, a deeply rooted love for—in fact, a veritable religion of—helping a fellowman out of his difficulties without regard to pay, time consumed or the opportuneness of the distress. Prinzhorn's prescription for compounding the ideal psychotherapist reads: "One wise priest from each of the great religious communities, one lawyer, one teacher, one psychologist, one wise philosopher, and three physicians possessing a very sound biological basis."

Friedrich Schultze-Maizier, in his article "Individualpsychologie und Religion," which appeared in Wexberg's *Handbuch der Individualpsychologie* (1926), wrote prior to but in a fashion quite similar to Prinzhorn: "Individual psychology is not religion—it is a science of the human soul which would work itself out in a practical way in psychotherapy and education, in social work and *Seelsorge*. Among its cardinal tenets belongs the doctrine of the 'blind spot' of egotism, of the pathology of all self-engrossed subjectivity, and of the healing power of a courageous subduing of egotism in service to society. Just this notion of society, which stands so rightly in the focal point of individual psychology-theory and -practice, leads necessarily to religious formulations of the problem. . . ." Individual psychology does more than re-echo New Testament truth; it gives modern psychological meaning to the words, "Whosoever will lose his life for my sake, the same shall save it. For what shall it profit a man, if he shall gain the whole world, and lose his own soul?"

The promptness with which the champions of religious psychotherapy proposed or accepted formulations of this kind can be attributed in large measure to the fact that centuries of religio-psychological inquiry in Europe had prepared the way with findings of corresponding import. From Xenophanes down, religious psychologists had defined first-hand religion in one way or another as an absolute valuation of something, with or without stipulating the nature of that something. By none was just this aspect of religion to be more brilliantly depicted than by Schleiermacher¹ (feeling of absolute dependence), Otto² (the *tremendum-fascinans* character of the holy), Stavenhagen³ (absolute attitudes), Augustin⁴ (innermost concern of an individual), and Mattiesen⁵ (self-abasement). Almost as far back in the history of European religious psychology are to be found intimations to the effect that this act of transcendently valuing something had to do in some way with the welfare of the soul, that such an act springs from a need for peace, serenity, security of the soul, that religion is at bottom a spontaneous psychohygienic, i.e., autopsychiatric, activity of the soul.

Socrates appears to have been the first among European religious psychologists to suggest a psychohygienic *raison d'être* of religion. The ultimate goal of religio-psychological yearning was in his opinion none other than the supreme good of the soul. Salvation of the soul from being carried away by the multiplicity and transiency of appearances, i.e., perceptual knowledge, he saw in a predilection for conceptual knowledge, i.e., wisdom. Salvation from being carried away by one's own desires and aversions he saw in a moderation of one's desires and aversions (i.e., in Σωφροσύνη). This moderation of the desires and aversions is best achieved through conceptual knowledge. Plato, his pupil, saw the goal of religio-philosophical yearning in the supreme happiness of soul attained through an inner contemplation of the ideal Good, True and Beautiful (*Phaedrus*). Religion for Aristotle had to do with the supreme good of the soul; that is, with reason's maintenance of peace of mind from the desires (*Eudemian Ethics*). Plotinus, the Neo-Platonist, discovered God, i.e., the supreme good of the soul, in the ecstatic feeling experienced during semiwaking contemplation (*Enneads*).

With the Stoics and Epicureans the connec-

tion between an absolute valuation and the soul's welfare was set forth even more explicitly. The motive to religio-ethical life they saw in the need for peace of mind, for imperturbability, for *ataraxia*, from the vexations of life within and without and particularly from the fear of death. They differed sharply as to the means, the Stoics attaching transcendent value to living in accordance with reason, the one and only way of not being carried away by appearances and by one's desires and aversions, the Epicureans claiming that peace of mind is only to be had through an exhaustive gratification of one's desires. According to Epicurus, even the gods of the people must be conceived as models of imperturbability and hence do not want to be disturbed with the complaints and petitions of human beings. Among Epicureans, Lucretius Carus (98-55 B.C.) held that true piety consists not in a cult of supernatural beings but in being able to view with calmness of mind the universe of nature and its concatenation of causes and effects. Death Lucretius regarded as a thing not to be feared but rather as something to be welcomed as affording an enduring peace "even gentler than a sleep without a dream." For Cicero, the Stoic, religion as a predisposition was a capacity and tendency to composure of mind under all circumstances whether in the contemplation of the world or in the struggle of life.

This thesis of the psychohygienic origin of religiosity is resumed from the seventeenth century onward but by none in Europe so clearly and decidedly as by Stürner, Ideler, Joly, de la Grasserie, Moerchen, Delacroix, Rank, Bergson and Spranger of the eighteenth and early twentieth centuries.

Max Stürner (Casper Schmidt, 1806-1856) in his *Der Einzige und sein Eigentum* (1845) regards the sacred as the most generic feature of religion and defines it as "everything towards which you cherish any respect or reverence." In reverence (*Ehrfurcht*) "something is not only feared but also honored: what is feared has become an inward power which I can no longer get clear of, I honor it, am captivated by it, and devoted to it, belong to it; by the honor which I pay to it I am completely in its power, and do not even attempt liberation any longer. Now I am attached to it with all the strength of faith: I believe. I and what I

revere are one; not I live but the revered lives in me!" The object revered possesses not only a fascination but also a certain foreignness. "In everything sacred there lies something 'uncanny,' i.e., strange, such as we are not quite familiar with and at home in."

This hallowing, this consecrating, this spiritualization of an object is at bottom the work of one's own Ego. Without this act of absolute valuation on the part of my Ego the object is as good as nothing. Once hallowed, the object becomes one with the Ego which hallows it. With full development of Egohood, the realization comes that at bottom the Ego hallows itself. That other Egos hallow an object means ought to me when my own Ego has attained its maturity.

Stürner sees religions differing in the object which is hallowed. Practically everything in nature or in supernature (speaks, thought-things) has been or can be held sacred by individuals. Thus a religion has been made of morality, chastity, speaks, ancestors, friends, love, reason, ideas, man, liberty, equality, communism, nature, marriage, patriotism, heroism, adultery, sex, one's vocation.

The hallowing of an object entails of necessity renunciation, sacrifice. Everyone who hallows something, no matter what, "ventures everything else for the one thing, one object, one will, one passion, etc."

As to the function of or motive to this consecration, to this enthusiasm, to this hallowing of and sacrificing to one object, Stürner believes it has, broadly speaking, to do with the welfare of the soul. Formerly it was a matter of finding a retreat for the soul from the vexations of life. With full fledged Egohood it is a matter of securing a freedom for the soul from the thrall of things alleged to be without one's power, from everything that is not you, not I—i.e., it is a matter of a self-realization of the Ego's ownership of the world. It is in self-realization that Stürner sees the ultimate salvation of the soul, i.e., of the Ego.

In Stürner's exposition of the psychogenesis and psychohygienic nature of religion is to be seen the most comprehensive formulation up to his time, if not in the whole of European religious psychology.

In *Versuch einer Theorie der religiösen Weltansichten* (1848 and 1850) the German psy-

chiatrist, Carl Wilhelm Ideler, observed both in his patients and in the lives of the great mystics of the past a compensatory, consolatory awakening of religious passions upon the shattering of life's happiness, particularly of love—a relationship which St. Francis de Sales had noted long before: "God is just as necessary to ungratified love as water to parched lips."

Henri Joly in *Psychologie des saints* (1898) saw the motivation to and goal of the saintly life in a higher integration of the personality (i.e., in a unity or at-one-ment) of the instinctual, emotional and moral selves. In this Joly differs from his predecessors, Maine de Biran and Jouffroy, for whom the higher at-one-ment, the Stoic-like peace of mind, was to be attained only by way of a complete suppression of the instinctive-emotional or animal self and for whom the spiritual life is identified with the moral life. Joly's conception of the saintly personality has more resemblance to present-day mental hygiene's notion of the wholesome personality. The saint is distinguished by Joly from the hysterical, despite the fact that hysterical phenomena are at times found associated with saintliness. Hysteria in the saint may result from imperfect integration, from suppression of the instinctual instead of its integration with the moral self. "Sanctity is not a disintegration." It is not a "division of the personality, although it certainly creates a new personality, and that at the cost of great sacrifice and much suffering. This new personality is not a medley of divided and dismembered parts. It exhibits a cohesion, a strength and a unity above anything which psychology can show us. This new personality also retains whatever was best of the original personality and these surviving elements combine peaceably within the new."

The nineteenth century came to a close with the work by Raoul de la Grasserie entitled *De la psychologie des religions* (1899) in which two categories of religion are distinguished: the *social* and the *psychological*. By *social* religion he means second hand or traditional religion, the notions and practices of which are stamped by the elders upon the young generation. By *psychological* religion he understands first hand subjective religion which springs as an ideal consolation out of instinctive-emotional needs frustrated of their natural gratification. De la Grasserie enumerates five instinctive-emotional

needs, any one or more of which may play, when frustrated, a leading role in the psychogenesis of subjective religion, namely, the desire for security (fear), desire for equality (justice), desire for companionship (social), desire to help the less fortunate (sympathy: for some the essence of piety is pity), and the desire to love. If a strong one of these vital needs is denied natural gratification, it may find ideal gratification in phantasy as for example in an imaginary companion, lover or protector suggested already in traditional religion or else created *de novo*. Here the psychohygienic origin of religion is seen as an ideal compensation, or consolation for instinctual privation in much the same sense as Ideler had noted.

At the turn of the century the American religious psychologist and founder of functionalism, William James, gave his Gifford Lectures at the University of Edinburgh entitled, *Varieties of Religious Experience* (1901-2) in which the psychohygienic theory of the origin of first hand religion received a most hearty endorsement. Here for the first time the term "mental hygiene" is actually used in this connection. Here the psychohygienic goal of religion is seen as the only common denominator of widely differing forms of religiosity. James defines first hand religion as a "live hypothesis" whose function, whose *raison d'être* is to assist one to live a happy life and to die a happy death. "I mean by religion for a man *anything* that for *him* is a live hypothesis in that line, although it may be a dead one for any one else" (*Pluralistic Universe*). The truth and reality of a religion can only be judged from the practical psychohygienic value it has for the individual concerned, constituted and circumstanced as he alone is.

This accentuation by James of the psychohygienic function of religion, of the role of religion in life- and death-adjustment, was to give, perhaps on a less tolerant scale, a definite cast to subsequent American religious psychology.

In Europe this Jamesian thesis along with its supersectarian character is mirrored rather faithfully by F. Moerchen in *Die Psychologie der Heiligkeit* (1908). A person designated as "holy" is according to Moerchen one who has seized upon something which he feels fills or makes whole a life otherwise left void by the

general run of worldly things. This something which so devoutly absorbs this person is regarded by this person as divine in the sense of "surpassing value." This something may be love, grief, enjoyment of art, enthusiasm for an idea, etc. As long as religion fills these unsatisfied yearnings and does so better than anything else and so long as unfulfilled yearnings persist in man, religion will continue to exist. When better religions come about in the sense of better satisfying unfulfilled human yearnings and needs, these religions will replace the old. The truth-content of religion must always remain a matter of individual, subjective conviction—"a fact of consciousness."

Implications of a psychohygienic origin of religiosity are found in *Etudes d'histoire et de psychologie du mysticisme* (1908) by Henri Delacroix. Based on the lives of St. Theresa, Madame Guyon, St. Francis de Sales, John of the Cross and Heinrich Suso this study reveals that the mystic in pretending to experience God is, in psychological language, experiencing an *alter Ego*, namely, the subconscious self with its automatisms such as hallucinations, glossolalia, intuitions, inspirations and compulsions. To the mystic this *alter Ego* which takes over appears to be of external and supernatural origin. In the presence of this apparently transcendent, impersonal subconscious self the personal conscious is passive, powerless, submissive. As these subconscious automatisms become "imperative and take possession of consciousness," they bring about there a new life-core, a superior unification. Probably the best analogy to this transformation of personality is that to be seen in a person experiencing romantic love. "The 'divine' is therefore a passive power of unification and organization which at first appears alien to the conscious Ego, owing to the division of consciousness." This impersonal subconscious reveals itself in the personal consciousness, progressively invades the latter and substitutes itself for forms of action and thought which constitute the personal consciousness. "This superior power, this substantial energy, this efficacious internal law, after being opposed to the conscious Ego, now penetrates it, assimilates the latter to itself, and creates a new life: it is an edifying power."

According to Delacroix this subconscious activity is determined by certain natural disposi-

tions and is regulated by directing ideas from traditional mysticism. This ideational content consists in "germs prepared by reflective consciousness and falling on a nature ready to receive them. This content matures and flowers without the subject perceiving anything of this work of maturation; the subject sees only the commencement and the end."

In the God experience of Oriental mystics an absolute negation of the conscious Ego and of the world, a suppression of all consciousness, is striven for. With Christian mystics all consciousness is not suppressed even in the ecstatic moment. On returning from ecstasy Christian mystics find themselves become a divine instrument, i.e., the conscious self implements the subconscious compulsion either to reexperience ecstasy through voluntary practice of asceticism, passivity, oration or else to carry out some generous endeavor.

At the base of mysticism Delecroix sees an effort to avail oneself of this "divine" i.e., subconscious power, to retrieve a primordial spontaneity so long imprisoned and mutilated in the course of ordinary life, to live without being held in check by the manifold and conflicting demands of every day life, to lift inhibitions, to let oneself go, to attain a grand simplification of life, to bring about a narrowing of consciousness, to have one's personality unified, to resign oneself to a will greater than one's own.

In *Das Trauma der Geburt* the psychoanalyst Otto Rank, claims the motivation to religious mysticism is a yearning to restore the whole-ness-state of prenatal existence in the womb. The instinctual tendency of primary significance is the will-to-wholeness which finds first its satisfaction in the womb-existence. Birth becomes the first shocking disturbance to this supremely satisfying experience of nine months "coitus" in which the unborn child, body and soul, formed a whole with the mother. Normally this birth-trauma terminates with the discovery of a new wholeness in the omnipotence of infantile narcissism. In adolescence this narcissistic wholeness is disturbed by the maturation of the sexual instinct which demands a sex-partner for a restoration of wholeness. Failure to satisfy the yearning for wholeness results among other things in a regressive longing peculiar to mystics who pine for a lost paradise

in utero matris. Thus would Rank interpret the yearning of a Tauler for a "return of the creatum to the uncreatum," of certain Sufis to be extinguished and like a drop to vanish in the "ocean of mystery," of an East Indian mystic to return to the alibidinous state of Nirvana.

Decidedly psychohygienic appear notions as to the origin of religion advanced by Henri Bergson in *Les deux sources de la morale et de la religion* (1933). Instinct is seen giving rise to a *dynamic* or *mystical* type of religion and intelligence giving rise to a *static* or *fabulatory* religion. Static religion is "a defensive reaction of nature against whatever in the exercise of intelligence might be depressing for the individual and dissolving for society." In other words the fabulatory function of the intellect furnishes a bulwark against the discouraging situations of which the intellect itself takes cognizance. This fabulatory function of intelligence works in an equilibrating fashion for the security and serenity of man and society. This static religion is hence of a mythological and philosophical character. On the other hand, dynamic or mystical religion, while equally affording security and serenity, does so through immediate intuitive experiencing of God who is in essence Love.

The cultural science psychologist, Eduard Spranger (1882-), implies a psychohygienic origin to religion. In his *Lebensformen* (1914) are distinguished six types of men (theoretic, economic, aesthetic, social, political and religious) according as one or another of these value-tendencies is dominant in the psychic constitution. The religious man values only that which can bring to his soul the highest and most permanent security and happiness. In *Die Psychologie des Jugendalters* (1924) Spranger even more broadly defines religion as "any *Lebensanschauung* in which only the individual concerned believes himself to have found the ultimate value of his life. Every life-content may move into this sphere of experience. One may hang his soul's salvation on his vocation and finally on mammonism. Psychologically all that is possible."

That the psychic imbalance of adolescence is just the soil for the germination of religiosity receives particular stress at the hands of a number of cultural science psychologists, notably Spranger,⁶ Kupky,⁷ Tumliar,⁸ Dehn⁹ and

Eichele.¹⁰ The few threats to the tranquillity of the young child are met by a budding religious feeling of absolute dependence on his parents. Only slowly, if at all, does he come before adolescence to transfer his feeling of dependence to invisible, supermundane beings of whom he has long heard much. Hebbel's childhood discovery on the occasion of a violent thunderstorm which did severe damage to his father's estate, that his father was not lord of creation as he had believed is a much cited example of precocious transfer of the feeling of dependence from the father to a supermundane agent. Normally it is the internal storm and stress of middle adolescence when maturing value-tendencies are struggling within for ascendancy that peace of mind is only restored with the eventual hierarchical organization of the value-tendencies, i.e., with "*persönliche Zuspitzung*." Momentary enthusiasms, fanatical monoideisms precede the discovery of a more permanent road to peace of soul which according to Eichele lies in one of three general directions: 1. a return to traditional religion; 2. a fashioning of a religion of one's own; 3. a selecting from traditional religion of that which appeals to him and an ignoring of the rest. The last solution is the most common one.

In *Psychologie der Religion* which appeared in Kafka's *Handbuch der vergleichenden Psychologie* (1922) Georg Runze leans decidedly towards the belief that religion is hardly intelligible save as a concern for the health of the soul.

How is the psychohygienic theory of the origin of religion to which so many in the history of European religious psychology have given their support to be reconciled with the numerous psychopathological phenomena so frequently associated with religiosity such as hallucinations, glossolalia, stigmatization, sadism, epilepsy, hysteria, psychopathy, morbid conscience, compulsion-neurosis, self-mutilations, melancholia, delusions of grandeur, introversion, autism, dementia praecox, delusions of persecution? Does not religion drive people insane?

The Danish psychiatrist, H. I. Schou, in *Religion and Morbid Mental States* (English translation 1926) has sought here to disentangle cause and effect. Schou argues that there is little evidence to support the widespread notion that

religion drives people mad. Religious influence is assigned as a cause of insanity in only ½ to 1 per cent of the cases in Danish "Annual Reports from the State Mental Asylums and St. Hans Hospital." In other words religious influence is very rare as a cause of insanity. The testimony of psychiatrists is cited by Schou to the effect that religion, instead of causing insanity, is in reality a safeguard against it (Oppenheim), affords comfort in adversity and reduces the danger of insanity (Krafft-Ebing), counteracts mental disturbance, depressed state of mind, and all the consequences of mental distress (Hyslop), provided the religion is a strong, true and firm faith. Of the three grand categories of mental illness—constitutional, physiogenic and psychogenic—it would be natural to expect that religion might heavily account for the production of the psychogenic but the actual fact is that even here only once in a hundred cases does that happen. Schou thinks the explanation of why so many people believe religion is a cause of insanity is in a confusion of cause and effect, in an erroneous interpretation of the fact that religious ideas are so extraordinarily frequent in the insane. Three causes are assigned by Schou for the frequency of religious ideas and experiences in the insane: 1. Traditional religious ideas imbibed from childhood at home and school, in church and confirmation-classes, at funerals and meetings, are latent in all of us. In the hour of need which is certainly the hour of psychical suffering these latent religious ideas make themselves felt. One then turns to the "old truths" for support; 2. For many people religious ideas imbibed are but a meaningless jargon, a sort of protecting charm which the sufferer stammers out in the dark night of mental disease, like a wanderer by night making the sign of the cross when he meets a ghost; 3. Mental illness reveals the total contents of the patient's consciousness, mercilessly bares the patient's soul including not just the meaningless jumble of religious ideas imbibed from traditional religion but also the primitive tendency, natural inclination, instinctive craving to religiosity which in normal times may be suppressed. Just here according to Schou is the breeding ground of religious genius.

That religiosity as a transcendent valuation of something, as an exclusive dedication of one-

self to something, as an absolute upon something is not always to be evaluated as conducive to mental health in the objective sense of that term has been recognized by a number of European religious psychologists who may or may not espouse a psychohygienic origin. Beginning perhaps with Socrates but very definitely with Lucretius, resumed many centuries later by Burton, Locke, Comte, Feuerbach, Marx, J. S. Mill, Isaac Taylor and Friedrich Nietzsche and continued into the present century by Bry, Schjelderup and Freud there has been clearly evidenced a tendency to distinguish "true" from "spurious" religious experience, not so much on the basis of their orthodoxy as on that of their psychohygienic efficacy. Accordingly, that religiosity appears to have been regarded as "true" which may be characterized as a positive consecration, i.e., one which is oriented towards objective reality, towards this world and particularly towards fellowman in some affirmative, constructive, ameliorative wise. On the other hand, that religiosity appears to have been regarded as "spurious" which may be characterized as a negative consecration, i.e., one which estranges from objective reality or which turns away from or against fellowman.

Lucretius, for example, considered belief in supernatural deities as originating in dreams and visions and ignorance of the causes of natural phenomena and adjudged reverence for such gods who have nothing whatsoever to do with the course of the world and its supreme principle of causality as not conducive to the calmness of mind which the contemplation of the universe and its concatenation of causes and effects or true piety gives.

St. Augustine gave in his *Confessions* a phenomenological description of his own religious conversion from lust of fame, of gain and of the flesh to love, humility and faith and told of his ultimate profit in peace of mind.

Robert Burton in *Anatomy of Melancholy* (1621) would distinguish as true religion that which "rears the dejected Soul of man, and amidst so many cares, miseries, persecutions which this world affords, is a sole ease, an unspeakable comfort, a sweet reposal, a light yoke, an anchor, and an Haven. It adds courage, boldness and begets generous spirits." Such a religion manifests itself in trust and gratitude. On either side of this healthy mean in religiosity

Burton in Aristotelian fashion sees standing two grand types of religious insanity: an excess of piety variously called superstition, idolatry, fanaticism, and a defect of piety called impiety, hypocrisy, libertinism, atheism. In excess-piety something actually of little consequence is so transcendently valued that demands of objective reality, of common sense and of human fellowship are entirely obscured.

John Locke (1632-1704) in Chapter XIX entitled, *Of Enthusiasm* of his *Essay Concerning Human Understanding* (1690) distinguished rational from irrational religion. The former is a love of truth for truth's sake. It is through the senses and reasoning based on sensory experience that "the eternal Father of light and fountain of all knowledge communicates to mankind that portion of truth which he has laid within the reach of their natural faculties." On the other hand it is pretended in irrational religion that knowledge of truth or God is come by in one of three ways: 1. a reliance upon authority rather than upon self-evidence or upon the force of demonstration; 2. an assuming of oneself as an authority for dictating to others and for prescribing their opinions; 3. enthusiasm, i.e., a reliance upon immediate revelation. Immediate revelation at the bottom of enthusiasm is "a far easier way for men to establish their opinions and to regulate their conduct than the tedious and not always successful labor of strict reasoning" and hence "it is no wonder that some have been very apt to pretend to revelation, and to persuade themselves that they are under the peculiar guidance of heaven in their actions and opinions, especially in those of them which they cannot account for by the ordinary methods of knowledge and principles of reason." Locke cites the manner of speaking of enthusiasts: they are sure because they are sure—and their persuasions are right because they are strong in them. These enthusiasts mistake feeling for seeing and set a greater store by the irrational than by the rational. Enthusiasm arises according to Locke in all ages in "men in whom melancholy has mixed with devotion or whose conceit of themselves has raised them into an opinion of a greater familiarity with God and a nearer admittance to his favor than is afforded to others" and "who flatter themselves with a persuasion of an immediate intercourse with the Deity, and frequent communi-

cations from the Divine Spirit." Whatever strong impulse these enthusiasts feel within them they conclude to be a call or direction from heaven and it must be obeyed as it is a commission from above.

Locke evaluates as sane only that religion which is a consecrated search for empirical truth.

Auguste Comte in *Cours de philosophie positive* (1830-1842) and in *Système de politique positive* (1851-1854), Ludwig Feuerbach in *Vorlesungen über das Wesen der Religion* (1845), Karl Marx in *Kritik der Hegelschen Rechtsphilosophie* (1844) and John Stuart Mill in *Utility of Religion* (between 1850 and 1858) distinguish as true or positive religion that which is a consecration of oneself to the amelioration of man's condition, a passion for social justice, a reverence for benefactors of humanity, and as spurious or negative religion that which is a worship of supernatural deities which are but figments of wish and phantasy. While the psychohygienic origin of religion is not expressly elaborated upon by these men, there is, however, implicit in their expositions the notion that religion is primarily concerned with the salvation of the soul. The kind of soul-salvation derived from negative religion they compare with that offered by dreams or opiates. For them positive salvation of the soul is by way of a consecration of oneself to social betterment. This kind of soul-salvation reminds not a little of the Bodhisatva-ideal of a renunciation of one's own salvation as long as there is left a single being in the world who suffers pain. For Feuerbach: "Man is to man the supreme being. Ethics is also religion"; for Karl Marx: "Man is the highest being for man" and "All conditions must be revolting in which man is debased, an enchained, an abandoned, a contemptible being"; for Mill: "The essence of religion is a strong and earnest direction of the emotions and desires towards an ideal object, recognized as of the highest excellence, and as rightfully paramount over all selfish objects of desire." For such a religious ideal Mill maintains that it is not "necessary to travel beyond the boundaries of the world which we inhabit." Such a positive religious ideal, as he sees it, is not the Epicurean "carpe diem" nor a narrow nationalism but "the idealization of our earthly life, the cultivation of a higher conception of

what it may be made." It is the cult of the positively ideal which can both exalt the feeling and ennoble conduct far better than any belief respecting the unseen powers.

Isaac Taylor (1787-1865) in his *Natural History of Enthusiasm* (1829) treats enthusiasm as a form of spurious piety. For him enthusiasm is an excessive enhancement of the value of an object by the imagination and desire. While he indicates that genuine religion involves sober enthusiasm for the realities promised in the Christian Testament, he maintains that the spurious form of enthusiasm is due neither to sobriety nor to defect of imagination but rather to an excess of imagination. Taylor characterizes the enthusiast as one in whom "the force and extravagance of the imagination is so great that it admits of no correction from even the severest lessons of experience, much less from the advices of wisdom; the enthusiast passes through life in a sort of happy somnambulism—smiling and dreaming as he goes, unconscious of whatever is fantastic: now he treads with naked feet on thorns; now plunges through depths; now verges the precipice and always preserves the same impassible serenity, and displays the same reckless hardihood." Whatever good of a psychohygienic kind comes to the individual from his monomaniacal enthusiasm may be attributed in the opinion of Taylor to the fact that "the object upon which the imagination fixes its gaze remains always unchanged and hence imparts a sort of tranquillity to the mind" and to the fact that this enthusiasm for some one object serves as "a refuge from the vexations of life."

In book after book, notably in *Also sprach Zarathustra* (1883), *Jenseits von Gut und Böse* (1886), *Zur Genealogie der Moral* (1887), *Der Wille zur Macht* (1888), Friedrich Nietzsche never wearies of driving home the distinction as he sees it between "true" and "spurious" religion. He sees all religion consisting in a sacrificial consecration to something and motivated by a will-to-power, i.e., by a craving for ego-satisfaction. Religion he defines as a case of the "*altération de la personnalité*," of the doubling of the personality into God and man, "when the feeling of power suddenly seizes and overwhelms a man." Nietzsche distinguishes two categories of sacrificial consecration: a positive one, namely, that to life-affirming goals; a

negative one, namely, that to life-negating goals. The former he endorses as truly conducive to the health and happiness of the soul; the latter he identifies with Christian asceticism which regards everything of this world as vanity and seeks salvation, peace elsewhere, i.e., "in nothingness ('God')." It is this anti-naturalistic kind of religion which Nietzsche downright loathes.

Christian asceticism, according to Nietzsche, is an unnatural striving on the part of the botched who are unable to triumph in life-affirming ways and who hence seek ego-satisfaction just in a morbid out-suffering of others, in peerless renunciation of life, in posing as "too good" for this world, in a holy form of debauchery. "The renouncer! What does the renouncer do? He strives for a higher world, he desires to fly farther and higher than all men of affirmation—he casts off much which would impede his flight, and many a thing which is nearest and dearest to him: he sacrifices it to his inordinate desire for altitude. This sacrificing, this casting off is now just that which becomes solely visible to him; accordingly one gives him the name of renouncer and as the latter he stands before us, wrapped in his hood and as the soul of a hairy shirt. With this effect which he makes on us, he, nevertheless, is probably satisfied: he wishes to keep concealed from us his lust, his pride, his aim to fly beyond us" (*Die fröhliche Wissenschaft* 1882).

On the other hand, Nietzsche cannot commend highly enough asceticism of a wholly other kind, a renunciation for the sake of worthwhile life-affirming goals and cites himself and his solitary consecration to the production of geniuses as an example par excellence of this kind of asceticism. Such renunciation not only brings true satisfaction to the soul but also makes possible the advance of human civilization. "I love those who do not seek beyond the stars for a reason to perish and be sacrificed but who sacrifice themselves to earth in order that earth may some day become Superman's." "I conjure you brethren, remain faithful to earth and do not believe those who speak unto you of superterrestrial hopes!" "I love him who willeth the creation of something beyond himself and then perisheth." (*Also sprach Zarathustra*.)

"Life-affirmation" does not mean for Nietzsche as it does for Albert Schweitzer a reverence for ordinary human life but rather a reverence for the choicest blossoms on the tree of life—for great men in whom the will-to-power, i.e., the life-force, comes to finest expression. "What is more harmful than any vice?—Practical sympathy for the botched and the weak—Christianity. . . ." (*Der Antichrist* 1895.)

That Nietzsche's great consecration of himself to the midwifery of genius was solely for the sake of his own soul's welfare is beautifully revealed by him in *The Great Longing*, the lines of which are here repeated:

"O my soul, now have I given thee all, and even my last possession, and all my hands have become empty by thee:—*that I bade thee sing*, behold, that was my last thing to give!

"That I bade thee sing,—say now, say: *which of us now—oweth thanks?*—Better still, however: sing unto me, sing, O my soul! And let me thank thee!"

"Thus Spake Zarathustra"

In the twentieth century there is Carl Christian Bry who points in his widely read book: *Verkappte Religionen* (1925) to a number of spurious or what he terms "disguised" religions: Esperanto, anti-alcoholism, theosophy, superman, communism, technology, youth-movement, success, anti-Semitism, Messiahship, will-training, statistics, psychoanalysis, Utopianism, environmentalism, race-hygiene, numbers, palmistry, pacifism, nudism and others. Bry maintains that these monomanias, these enthusiasms, offer, temporarily at least, a refuge, a consolation, a kind of salvation to humans who flee the struggle of life instead of fighting it out.

The Norwegian religious psychologist, Kristian Schjelderup in his *Die Askese* (1928) distinguishes three forms of mystical experience striven for by way of genuine asceticism: 1. *elevation-mysticism*; 2. *regressive introversion-mysticism*; 3. *sublimation-mysticism*. In elevation-mysticism the libido, being withdrawn from concrete outer objects and turned inwards, is transferred to an object of phantasy as exemplified in erotic dalliance with the Heavenly Bridegroom. In regressive introversion-mysticism the libido, being withdrawn from outside objects and turned inwards, regresses to the nar-

cissistic stage in libido-development (*ego-libido*) as exemplified in Zen-Buddhism or in the mysticism of Angelus Silesius or else it regresses to other early stages in libido-development as seen in the mystical yearning for the scenes of one's childhood peculiar to Anker Larsen or in the Mother-yearning of Ramakrishna or in the womb-yearning of Tauler and Sufi-mystics. In sublimation-mysticism the introverted libido is chastened and re-extroverted in the form of a passion for a work of a socially beneficial nature as exemplified in religion as *charitas*, enthusiasm for social justice, etc.

While recognizing serenity of soul as the ultimate goal in all these forms of religious mysticism, Schjelderup evaluates from an objective standpoint elevation-mysticism and regressive introversion-mysticism as mental pathological and non-social. Sublimation-mysticism he views on the other hand as mentally wholesome and socially valuable. His evaluations are corroborated by the testimony of many a great mystic like John of the Cross, who after long experience with introversion-mysticism revealed that atop the summit of the mountain there is "nothing, nothing, nothing, neither grandeur, nor security, nor satisfaction, nor consolation, nor insight, neither pleasure, nor freedom, nor honor, nor knowledge, nor peace, nothing, nothing, nothing, nothing" and who found only in active charity, in checking the misery of fellow-man ultimate peace for his own soul.

Sigmund Freud's life-long contention that religion of the theistic variety is a compulsion-neurosis, an overscrupulosity, a sort of touch-piece against libidinous impulses, his position taken in *Die Zukunft einer Illusion* (1927) that such religion cures the minor neuroses of life only to leave the individual with a grand superstition and his anti-religious stand expressed in this work—namely, that now with the wonderful progress of scientific psychotherapy this outmoded supernaturalism should go the way of all prescientific nostrums must, however, not blind one to the fact that in many places in his works he endorses as truly psychohygienic an entirely different kind of religion—namely, a sublimation-religion which is a re-extroversion of the libido transformed into a passion for some socially valuable work.

From these several distinctions it appears possible to glean that forms of consecration which

evidence objective orientation (or what Bychowski¹¹ regards as a happy blend of subject-object), extroversion, *Gemeinschaftsgefühl*, life-affirmation have been evaluated as "true," i.e., mentally wholesome, while those featuring flight from reality, life-negation, immurement within oneself or within one's subconscious, introversion, estrangement from or hostility towards fellowman, morbid conscience, war against one's animal instincts, refuge in phantasy, in solitude, in meditation, in soliloquy, in memories, in utter forgetfulness, in drugs or in suicide have been evaluated as "spurious," i.e., psychopathological.

How are these "spurious," i.e., psychopathological, forms of religiosity to be reconciled with a psychohygienic theory of the origin of all religion? It appears that the evaluations themselves are to blame for this seeming paradox.

In the first place it appears that instead of evaluating religions as either "mentally wholesome" or else "psychopathological," it would be nearer the truth to speak of them as being either more or less mentally wholesome. It will be recalled that Isaac Taylor, Nietzsche, Bry and Freud expressly attributed some psychohygienic value even to the so-called "spurious" forms of religiosity. Max Stirner went so far as to claim that all forms of religiosity have to do with the welfare of the soul, some better than others.

In the second place the evaluations are in error when they confuse psychohygienic values with ethical, i.e., altruistic, values. The two kinds of values need not always coincide. Religiosity, despite its frequently altruistic manifestations and despite even at times its manifestation as a group-polarization, is at bottom a selfish, i.e., private, concern in the sense that it originates in the soul of the individual and is designed just for the good of this individual's soul. That others may benefit by or be involved in an individual's consecration of himself to something is not the thing of prime importance but rather whether this consecration like any other brings peace of mind to the individual concerned.

In the third place the most serious error in those evaluations of religions into "mentally wholesome" and "psychopathological" is their obvious onesidedness in viewing mental health exclusively from an objective standpoint, i.e.,

from the outsider's point of view. Such a bias of necessity makes for a psychohygienic devaluation of those forms of consecration which are not oriented towards objective reality and towards fellowman yet which bring unspeakable peace, happiness, serenity to the troubled soul of the individual. With such a bias one comes no closer to the true nature of religion than does the American, Henry Link, in his widely read book, *Return to Religion*, in which religion is identified with church-going and hence evaluated highly as an extroverting influence. How with such an objective bias as to the nature of mental health is one to understand save as "fools in Christ" men like John Brown and Franzos' "Taras" ¹² whose holy passion for social justice required of them the sacrifice of everything ordinarily held dear.

No, mental health is an inner condition which cannot with certainty be known from outside. Psychohygienic evaluations of no matter what form of religiosity must be made not from the *Gegenstandseite* but only with certainty from the *Ichseite*. That a conviction, a consecration, an enthusiasm is objectively oriented is wholly incidental. The thing of preeminent significance is that this or that enthusiasm—no matter whether a naive solipsism or an equally naive communism, no matter whether a materialism like behaviorism that would make a religion of denying the existence of the soul or a spiritualism like Christian Science which would make a religion of denying the existence of body—brings inward peace, serenity, happiness to one's soul and brings it better than anything else in the world.

Inasmuch as this peace of mind is an inner state, it must be subjectively experienced in order to be known. Hence immediate knowledge of it is limited to one person in the world. To the outsider is granted only a mediate knowledge of it through *Einfühlung*, i.e., intuition, provided a kinship of souls exists.

Fellow persons, who alone have the immediate experience of this peace of soul, either in passivity or in activity, have been confronted with difficulty in communicating their experience to others, save in metaphors and parables. Such phenomenological descriptions as have been left us in autobiographies and confessions have revealed it as a "glorified joy," as "sweetness," as an illumination, as a restoring of the soul, as a peace that passeth all understanding,

as a flight of the soul, as a lifting of the burden, as a self-effacement, as sheer bliss, as grandeur of the soul, as the precious pearl, as the gold sack, as the Kingdom of God within, or simply as God. Plotinus ¹³ compared it to the ecstasy of sex union. Meister Eckhart says that it is "the kingdom which the poorest man possesses." Ramakrishna ¹⁴ likened it to "that happy state of comfort felt by a fatigued worker when, reclining on a pillow, he smokes at leisure after a hard day's toil: it is a cessation of all anxieties and worries." A Sufi text portrays the peace of Nirvana: "I have been effaced, I have vanished; nothing has remained of me. I was a drop, lost in the ocean of mystery, and now no longer do I find even this drop." For the Zen-Buddhist the realization of Buddhahood is simply the attainment of equilibrium and harmony of the soul, to the point that one remains calm and cheerful even in the raging struggle of the battlefield, that one sleeps amid the howling of the storm and that even in the presence of death one composes his most beautiful song. "Call the divine how you will, call it God, Allah, Jahweh, Brahman, call it Creator, Nature, or Substance—it is all the same: empty noise and smoke." ¹⁵

This inner peace of soul has been described by those who have come by it through a reverence of nature. For example, the mystical experience of a glossolalia patient, when high up in the mountains or at other times, is reproduced in her own words by Kristian Schjelderup: "Happiness; no anxiety; absolute harmony. I no longer think—I no longer am an individual self. When one walks, one walks and it is nothing more therein than just walking. No demand, no desire is there—only the pronounced feeling of being one with everything else. In this state I am simply everything else. I am the light, I am the snow, I am what I hear." ¹⁶ Strikingly similar is the experience of James Russell Lowell, expressed in his "Under the Willows":

"My soul was lost,
Gone from me like an ache, and what remained
Became a part of the universal joy.
My soul went forth, and, mingling with the tree,
Danced in the leaves; or, floating in the cloud,
Saw its white double in the stream below;
Or else, sublimed to purer ecstasy,
Dilated in the broad blue over all.

I was the wind that dappled the lush grass,
The tide that crept with coolness to its roots,
The thin-winged swallow skating on the air:
The life that gladdened *everything* was mine."

Among Christian mystics Teresa di Jesu writes: "Ecstasy has a consequence, a remarkable separation from the world, so profound, so radical, that I am unable to describe it." Yet elsewhere she says: "The feeling and sweetness in mystical ecstasy are so extraordinary that one can find nothing to compare with it. If the memory of it were to persist, the soul would always have to feel a loathing for the joys here below; hence it comes also that it thinks little of all things of the world." Madame Guyon, in *Spiritual Torrents*, writes: "But here the soul is raised, as it were, to a mountain top, from which it sees the waves rolling and tossing, without fearing their attacks; or rather it is at the bottom of the sea, where there is always tranquillity, even while the surface is agitated. The senses may suffer their sorrows, but at the center there is always the same calm tranquillity, because He who possesses it is immutable." For the more commonly quoted experiences of religious mystics one should see *Ekstatische Konfessionen* (1908), compiled by Martin Buber.

With the exception of men like St. Augustine and Max Scheler, and perhaps all those philosopher-psychologists before the twentieth century who solipsistically universalize their own immediate experience of religion, European religious psychologists have sought indirectly through *Einfühlung*, i.e., sympathetic understanding, to interpret the religious experiences of others as revealed in their confessions, autobiographies, diaries, essays, poems, conversations, answers to questionnaires, dreams and protocols of systematic introspection.

What does this mediate or immediate knowledge on the part of European religious psychologists reveal? If their many and varied insights over many centuries have any anchorage at all, it appears to be something like this: First-hand religion, whatever its phenotype, is a solemn concern of an individual for the welfare of his soul. An individual is on the threshold of religion when the question, "What shall a man give in exchange for his soul?" moves into the focal point of his concern. In a transcendent, i.e., absolute, valuation of the soul and its welfare or of some means to the welfare of the

soul appears to consist the *sine qua non* of all spontaneous God-consciousness. God or Brahma is ultimately "the soul itself which has found its own grandeur" (Otto).

To value something transcendentally, i.e., absolutely, is, according to Stavenhagen, "Absolute Stellungnahmen," to enhance the value of it to the altogether different *ganz anderes*, i.e., to the no longer comparable. This *ganz anderes* character, which an absolute valuation bestows upon its object, gives to it the appearance of being outside of the world, i.e., as being supermundane. The term *sacred*, *holy* or *divine* is reserved as a designation for the object of transcendent, i.e., absolute, valuation.

An absolute valuation evidences itself in a strange fear and fascination (Otto), in an utter reliance (Schleiermacher), in a total subordination of oneself (Prinzhorn, Mattiesen), in an innermost concern with (Augustin), in a *persönliche Zuspitzung* (Eichele), in a consecration or dedication of oneself to, in an exclusive devotion to, in a magnificent compulsion or obsession variously called an enthusiasm, a fanaticism, a monomania, a monoidism.

Religious experiences appear to differ first of all with respect to whether the soul and its welfare (idealism, spiritualism, romanticism), the means to the welfare of the soul (theism, supernaturalism, fetishism) or the indistinguishable blend of the means-end (the *unio mystica* of pantheism and religious mysticism), is the transcendentally valued object. Most common is the religious experience in which the means to the welfare of the soul is transcendentally valued and here religious experiences differ most widely as to what this means is.

Genotypically speaking, first-hand religion, according to European religious psychologists, appears to be a biopsychic function, a spontaneous psychohygienic activity of the soul for retrieving its whole-like-ness, its equilibrium, its equanimity, its autonomy, its serenity, its at-onement, its grandeur. Serious need for a restoration of this peace of soul, either in activity or in passivity, arises in the presence of a bewildering confusion of external impressions, insufferable oppression from without, impediments to self-realization, insurmountable obstacles, boredom, fear, anxiety, perplexity in the solution of life problems, indecision as to a course of action, the menace of instinctual tendencies, the imbalance resulting from momentary

about them, possess nevertheless a secret religious life of their own. Obviously each individual has to be left alone for his soul to work out its own salvation, in so far as that does not prove a source of real harm to others. This appears to be consonant with the truer meaning of religious freedom, of religious tolerance.

To consider religion as peculiar to an earlier stage in man's cultural evolution, as a stage which has been now definitely transcended, as does Lévy-Bruhl in all his works, is to evidence a shocking lack of familiarity with the genotypical in religion. Obviously Lévy-Bruhl and, shall we say, Comte and Freud have in mind a phenotype of religion; namely, supernaturalism wherein a man's soul salvation is derived from supplicating allegedly supermundane agencies. As has been gleaned, many varieties of religion have been evolved as ways to the salvation of the soul, of which supernaturalistic ones may justly be considered among the more primitive. From an evolutionary standpoint religiosity assumes, in the most highly civilized of men today, forms which have little outward resemblance to its more primitive manifestations. Max Stirner aptly compared the phenotypes of religion to the skins of a snake; as soon as the snake-skin of the old religion is shed, a new religious snake-skin takes its place. Carl G. Jung has put the matter this way: "The living spirit grows and even outgrows its earlier forms of expression. The living spirit is eternally renewed and pursues its goal in manifold and inconceivable ways throughout the history of mankind. Measured against it, the names and forms which men have given it mean little enough; they are only the changing leaves and blossoms on the stem of the eternal tree" ("Modern Man in Search of a Soul"). What appears to be perennial in religion is the need for peace of soul; what is ephemeral is the means to that end. At higher evolutionary stages of religion the unconditional means to peace of soul has been found in a love for the brother whom one hath seen; God has become man. Nietzsche's observation, "the profoundest misunderstanding of religion: 'evil persons have no religion,'" is no less a fact than its paraphrase, "the profoundest misunderstanding of religion: 'persons who do not reverence supermundane beings have no religion.'"

The newer religions, which bring soul salva-

tion through a love to others, have the double advantage of peace to the soul of the individual and of positive benefits to others. In them "man gets his salvation," according to Ramakrishna, "when his egoism dies." With religious maturity so many Christian mystics got their salvation, as Schjelderup has pointed out in what they themselves have termed "spiritual marriage," i.e., in a consecration of themselves to works of charity.

The singular thing is that so many of those professing Christianity have not arrived at the religious maturity called for, i.e., at obtaining peace of soul through some form of love to others. Rather, these may remain stuck in more primitive forms of religiosity, having little or incidental connection with the neighbor-love principle of Christianity. These make a maze of superstition, fetichism, emotional release (getting happy), stigmatization, baptisms, circumcision, castration, flagellation, world flight, hermit life, speaking in tongues, the wounds of Christ, relics, repentance, persecution of Jews, pilgrimage to the Holy Land, papistry, Jesuitism, witch persecution, Holy Warring, inquisitorial sadism, imaginary sex relations with Jesus, polygamy, celibacy, asceticism, survival after death, communication with the ghosts of the departed, icons, lambs, doves, Mary, the infant Jesus, theophagy, supernaturalism.

Whether the means fervently resorted to by the soul for the sake of its welfare be adjudged high or low on an evolutionary scale appears after all to be of secondary moment as long as whatever this means happens to be pacifies the soul of the individual and does it better than anything else. At bottom, religion appears first, last and always to be an effort on the part of the soul to preserve its composure, whether in the struggle of life or in the face of death.

Such appears in brief to be the interpretation of religion which has run through centuries of religio-psychological inquiry in Europe. For ages denounced as heretical, atheistic, anti-religious on account of its leaning towards a this-world salvation of the soul, and on account of its scepticism with respect to supernaturalism being the exclusive means to such salvation, this psychohygienic interpretation of religion received scant recognition of a positive kind until the twentieth century, with the scientific undermining of supernaturalism, with the over-

coming of medico-psychological materialism, and ultimately with the *rapprochement* of *Seelsorge* and the new scientific psychotherapy.

REMEDIAL READING.—*History.* The latter part of the nineteenth century marked the consideration of reading in a new light. Laboratory experiments were carried on in the fields of perception, eye movements, reading hygiene, eye-ear-voice relationships, inner speech, rate, and comprehension.

From 1910 to the present, increasing emphasis has been placed on the educational importance of reading. Laboratory experiments *per se* gave way to investigations carried on for a definite educational purpose. Standardized group and individual reading tests were developed and used extensively. Experimentation revealing important differences between the techniques employed in silent reading and those used in oral reading led to emphasis upon training in silent reading for elementary school children. Consideration of the importance of individual differences in all aspects of the learning experience resulted in individualization of reading instruction.

An outcome of laboratory and classroom analyses of the reading process was an interest in the types of reading disability and their diagnosis. Remedial programs have been developed to correct deficiency in comprehension, rate of reading, eye movements, and vocabulary. Reading clinics are in operation in ele-

mentary schools, high schools, and colleges, where individualized remedial training is given. In many schools a combination of individual and group instruction is used at these three levels, which provides for progress of the individual according to his ability.

Indicative of the great increase in interest in reading techniques instruction and remedial work is the fact that since 1911 over two thousand studies have been made in the field of reading.

BASIC PRINCIPLES

There are certain principles upon which current undertakings in remedial reading are based. They are an outgrowth of experimentation and analysis in the fields of physiology, psychology, and education.

1. Examinations to determine the nature of the reading disability precede treatment for the apparent reading deficiency. Diagnosis reveals the cause and type of disability.

2. Before a remedial program is designed for the individual, there is a study of his total personality, including intelligence, educational history, physical and emotional condition, and family background.

3. Whether the remedial program be constructed for the individual or for a group, it is flexible and personalized so that the pupil may be motivated and instructed according to the level of his ability and the nature of his reading disability.

4. The pupil is motivated by an understanding of the purpose of the remedial instruction, by knowledge of his progress, and by a point of view which leads him to approach the undertaking not as a discipline or a punishment but as an interesting experience.

EXPERIMENTAL WORK

Perception. The discovery by Valentius in 1844 that the reader perceives three or four letters simultaneously was followed by experiments by Cattell (1885) proving that words are perceived as wholes and not by letters. Erdmann and Dodge (1897) showed that words can be recognized when the individual letters are too small to be identified or when parts of the word are out of the range of clear vision. They reported that there is no perception during eye movements.

Eye Movements. Javal and Lamare (1879) first recorded the observation that the eye moves across the page by little jerks instead of moving continuously. Dodge (1898) constructed a camera with which eye movements were photographed. Several investigators built cameras similar to the one first used by Dodge, but the construction of the portable binocular eye-movement camera in 1932, built by C. C. Taylor and J. Y. Taylor, brought radical changes in the study of eye movements. The films show regressions, return sweeps from the end of one line to the beginning of the next, the length and number of fixations or pauses, as well as such disorders of the eye as strabismus and nystagmus.

Inner Speech. Huey (1898) studied the tendency in silent reading to articulate the words as they are read, and concluded that vocalization tended to interfere with efficient and rapid silent reading. Studies by Pintner (1913), C. T. Gray (1913), and others confirmed Huey's conclusions that articulation in silent reading is a common habit but not necessary.

Rate and Comprehension. Analyses of the relation of reading rate to comprehension accompanied the construction and widespread use of standardized silent and oral reading tests from 1911 to 1930. It was found that the rate of reading varies with the purpose for which the material is read, the content of the material, and the level of difficulty of the vocabulary used in the material. C. T. Gray (1917) showed that the most efficient reading is not necessarily the most rapid. Peters (1917) and others reported that speed drills for elementary school children resulted in increased rate of reading without an appreciable loss in comprehension.

General. Of great value to the students of remedial reading have been the studies in the fields of motivation, learning, maturation, habit formation, emotion, and mental hygiene.

APPLICATIONS

The wide range of experimentation in the field of reading during the twentieth century led to the realization that remedial programs could be devised at all educational levels, and that failures in various academic subjects might be traceable to inefficient reading habits. Not only is attention given to the cases of extreme

reading difficulty, but also to individuals in elementary school, high school, and college who lack average proficiency in reading. Concomitant with diagnosis and treatment of reading inefficiencies is instruction in study habits.

Diagnosis of an individual's reading difficulty includes examinations to determine visual acuity, general physical and emotional condition, mental age, and intelligence quotient, as well as the nature of the reading deficiency. Treatment is arranged on the basis of these findings, and emphasis is put upon arousing the pupil's interest in reading by selecting materials at his reading level which also fit in with his interests and activities. Whether group or individualized training is used, the evaluation of progress is based upon the known facts concerning the pupil.

The importance of perception in reading and the understanding of the purpose for which the material is read are taken into consideration in developing in the pupil understandings of sentence, paragraph, and chapter structure. Flash cards and word lists are used to increase the pupil's vocabulary, and experience is provided in determining the meaning of an unfamiliar word by studying it in context.

Studies of the photographs of eye movements resulted in the belief that rhythmic movements with relatively few fixations indicated efficient reading. Such devices to facilitate even, smooth reading, as slides, motion pictures, and the metron-o-scope, have been used successfully. They enable the instructor to control the speed of reading and help the pupil to form the habit of regular eye movements and to break the habit of vocalization.

The evidence from experimentation that poor silent reading is often accompanied by poor oral reading has led to the use of various oral reading tests as a diagnostic technique to discover tendencies toward reversals of letters and words, omissions, addition of syllables, misunderstanding of punctuation, and vocabulary limitations.

TRENDS

Experimentation in the field of reading has established proof of the fundamental nature of the reading process and of the possibility of remedying deficiencies in reading rate and comprehension. Specialists are engaged in continued

research and experimentation to refine procedures of diagnosis and treatment. Standardized diagnostic and reading tests are under scrutiny. Studies are being made to determine the relative value of different types of group remedial programs. The advantages and disadvantages of individual remedial programs are being enumerated and weighed. The complexity of causes of many reading difficulties is recognized and the aid of psychiatrists, social workers, psychologists, oculists, and medical doctors is being sought in order to improve diagnostic and remedial techniques. Resulting from data presented by specialists in these fields is experimentation with different types of book formats, lighting, and teaching methods. In pre-service and in-service training of teachers, instruction is provided to increase the probability of detecting early the retardation in reading ability, thereby preventing the development of inefficient reading habits or of unfavorable attitudes toward reading.

APPLICATIONS OF THE KNOWLEDGE

The accumulated information about reading disabilities has led to certain important applications. Evidence that reading disability may be due to defective vision caused by glandular disturbances, contagious diseases, etc., has led to emphasis on the importance of periodic medical examinations, including thorough tests of visual acuity. Analyses of the success or failure of numerous remedial programs have substantiated the findings of psychologists regarding the significance of the pupil's emotional and attitudinal set in a learning situation. They have also indicated strongly the importance of the personality factor in teacher-pupil relationships. It has become evident that much remedial work would be unnecessary if reading were well taught in the primary grades and if the more complicated reading techniques (skimming, reading for appreciation, analysis, etc.) were explained and practiced at suitable grade levels. Case studies have shown that the difficulty with reading may be a cause of a variety of personality maladjustments or a result of emotional disturbances. These facts have reinforced the thesis of psychiatrists and psychologists that the child functions as a whole, a composite of emotions, attitudes, abilities, in any learning situation, and that his education

cannot be thought of as an isolated experience distinct from his home life or his play life.

RORSCHACH METHOD.—I. **METHODOLOGICAL CONSIDERATIONS.** A general description of the Rorschach method and its background has been adequately given in a preceding article.* Dr. Symonds has distinguished between the unstructured projective techniques, which are best suited for formal analysis, and the structured techniques which lend themselves more to content interpretation (cf. Symonds, pp. 583-589). The Rorschach method is certainly best known for its adaptability to formal interpretation, but content analysis is increasingly recognized as an integral part of Rorschach interpretation. The Rorschach method may be said to fall midway between structured and unstructured techniques.

It is not accidental that Rorschach paid more attention to the formal aspects of the inkblots and the way people respond to them. During ten years of experimentation he carefully chose the stimulus material in such a way that the formal aspects could be systematically delineated. The semi-structured quality of the blots, as contrasted, for example, with cloud pictures, consists in their quasi-symmetry and in the careful distribution of the stimulus material. There is a deliberate variation in the compactness of the blots, for example, in the use of color and shading and in the ease with which they lend themselves to a reversal of figure and ground. Cloud pictures in comparison lack these elements of structuralization which increase the meaningfulness of the blot material and hence the significance of the content of responses. And while there is a growing interest in the formal analysis of responses to the Thematic

Apperception Test, the task is more difficult than in the Rorschach test because the extreme meaningfulness of the figures focuses attention on the corresponding meaning of the stories.

II. PERSONALITY ASPECTS REVEALED IN RORSCHACH RESPONSES

A. The Qualitative Aspect of Intellectual Functioning. The results of psychometric tests such as the Basil Age and Scatter—the specific successes and failures on these tests—very often become more meaningful when considered in conjunction with Rorschach findings. The quality of intellectual functioning is determined in the Rorschach method mainly from the particular blot areas selected for responses, the manner of organization, degree of accuracy, and degree of specificity of concepts perceived. (Cf. paper by Klopfer and Davidson [3], where the authors describe how the distribution of W's and D's and the form level of a record offer valuable information regarding intellectual functioning.)

(1) With Subjects of superior intelligence, the Rorschach method shows, for example, whether thinking is more inductive or deductive. It becomes apparent if a Subject uses his best capacities or attempts what he is least able to do, as, for example, when a person gifted for detailed observation and precision work wastes his energies in an abstract or generalizing approach. The Rorschach material shows to what extent creative impulses are developed or suppressed, and whether the Subject uses them to enrich thinking or lets himself be carried away by them to the detriment of logical reasoning.

(2) At a low average intellectual level, Rorschach evidence may answer the important question of whether the poor performance is due to a general limitation of capacity or to a one-sided intellectual development, which is often a contributing factor in reading difficulties. Infantilism may show up as the condition interfering with intellectual development, or a severe emotional disturbance for which intellectual functioning serves as a battleground. In other cases poor intellectual performance may be attributed to mental deterioration resulting either from an organic process or from progressive loss of intellectual and emotional contact with reality.

B. Emotional Functioning of Personality.

* See PROJECTIVE TECHNIQUES.

may be baffled by the presence of the color and try to avoid it, or react to it in an excited, tense manner. In contrast, both the extremely well-adjusted individual and the psychotic rarely show any such discomfort in dealing with color. The psychotic may not respond to the color at all, or may use it in a peculiar, bizarre manner, but he will not be subjectively disturbed by it.

(4) *Dynamics of Inner Life.* The specific contents of a Subject's fantasy life are more clearly revealed through techniques like the Thematic Apperception Test than through the Rorschach. However, the general role which fantasy activity plays in the thinking and feeling of the Subject reveals itself quite easily in his Rorschach record. The more "promptings from within" are accepted as a valuable or even creative contribution to his thinking the more the Subject permits the inkblots to take on action—human, animal, or inanimate. The meticulous, over matter-of-fact mind frequently shows a suspicious attitude toward any concept not entirely under rational control and is correspondingly loath to project any action into the blots.

The responses projecting human-like action reflect a person's fantasy and the nature of his attitudes toward his role in life and his relationships with others. Up to eight years of age, action elements are almost entirely limited to animals, partly for reasons of intellectual maturation and partly for reasons of emotional development. In an adult the number and quality of animal-movement answers mirror the Subject's way of expressing or repressing the "promptings from within," known as "instinctive drives" or "animal impulses." If these impulses are not accepted as a valuable, functioning part of the personality, but are felt within the Subject as unintegrated, hostile, autonomous forces, he tends to envisage inanimate movement in the inkblots. The anticipation of conflict between the goals of instinctual needs and the demands of the environment seems frequently to be indicated by the projection of such inanimate movement, of abstract forces over which the Subject has no control.

III. AREAS OF APPLICATION

If the Rorschach method is taken for granted as reliable and generally trustworthy it is not hard to see where it can be useful.

A. It has been applied most extensively in the field of psychology for differential diagnosis, to distinguish between neurosis and psychosis, and to identify the various types of mental disorders. Rorschach responses have been found to reflect the implications of somatic difficulties ranging from the severe interference with personality functioning caused by cortical lesions of the central nervous system, through the more indistinct effects of subcortical disturbances like encephalitis and cerebral palsy or ideopathic epilepsy, to the intricate, interwoven factors associated with the psychosomatic disorders.

From a therapeutic point of view the Rorschach method is useful for prognosis and treatment planning. It can answer questions regarding whether a Subject is analyzable, what may be the effects of shock treatment on a psychotic patient, or what is the possibility of alleviating somatic symptoms through psychotherapy.

In research the method is being applied to such problems as whether there is an "epileptic personality," and whether certain personality types are prone to accidents or certain illnesses.

B. In the field of child development and child guidance the Rorschach method is increasingly useful. For longitudinal studies of personality development it is of particular value at the early pre-school stage when verbalization and introspection are limited. In guidance programs it is an efficient adjunct to psychometric techniques. The method, when used like an X-ray to investigate the structural underpinning of observable behavior, may show, for example, that marked behavior disturbances are not paralleled by equally serious disturbance underneath, while mild surface disorders may prove to be the early symptoms of organic pathology. (The problem of incipient schizophrenia is one of the plagues of child guidance agencies.)

C. *Social Work.* Many of the same problems confront social work agencies and there too the Rorschach method is being applied more and more as an aid in their solution (cf. 4). In particular it is of service in distinguishing the cases where difficulties in social adjustment are mainly the repercussions of personal maladjustment from the cases where some manipulation of the environment might suffice to allow the people to help themselves.

D. *Vacational Guidance and Rehabilitation.* While the Rorschach method cannot be used as a mechanical scaling device to find out what

kind of jobs people are fitted for, in an individual guidance situation it is very valuable in conjunction with the usual tools of vocational guidance, such as interest blanks and aptitude tests. The results of such tests may be better understood and applied when they are related to the specific strong or weak points of an individual's intellectual and emotional make-up as revealed in a Rorschach test. Personality characteristics which are favorable or unfavorable for success in a particular job may be pointed out on the basis of Rorschach findings.

E. Personnel Work. In the application of the Rorschach method to personnel problems, striking successes have been achieved in the selection of personnel and in cutting down turnover when the examiner has been able to combine his detailed picture of the applicant with a detailed knowledge of the job situation. Attempts to delineate Rorschach signs as a screening device for particular types of jobs have proved unsuccessful.

F. Anthropology and Sociology. Anthropologists and sociologists have experimented with the Rorschach technique and demonstrated its value as an instrument for comparative group study (cf. 2). In *The People of Alor*, Oberholzer made the first thoroughly systematic use of the method in anthropological research (1). The culture-free nature of the test becomes apparent as it yields results even from Subjects

of non-literate cultures. The meaning of the personality aspects revealed by the Rorschach in terms of actual behavior is, of course, modified by the cultural situation. For example, in a comparative investigation of five American Indian tribes, it appeared that the Zunis were particularly different from the other tribes in their extreme reliance upon inner resources and their complete absence of any desire for conquest. These characteristics are historically illustrated by the fact that the Zunis were so anxious to keep out of intimate contact with other human beings that they moved to the top of a mesa where living conditions were considerably more difficult.

SEMANTICS, LANGUAGE.—Sec. 1. *Complex Nature of Language.* The word *semantics*, created by Bréal, is used in three senses. In the first sense, for which Locke and De Saussure use the term *semiology* and the Americans rather *semiotics*, it is the study of signs in general, such as writing, the alphabet of the mutes, symbolic rites, heraldics, military signals, etc. In the second sense (in which L. Bloomfield uses it), it is the study of *meaning* in language; that is, of the semantic value of grammatical and lexical units. In the third sense (which is the traditional one, starting with Bréal, *Revue des Deux-Mondes*, June 15, 1897), it includes only one section of language; that is, lexicon. Here we shall use the term *semantics* in the second sense.

Language, however, is not only a branch of semantics; it is much more than a mere medium of communication between men; it is also a means of expression, and, as such, it is art, as we shall see.

Language, like all social or "moral" phenomena (as the Italians say) which deal with man, is a very complex fact. It offers many complicated problems which we do not yet completely understand. Several conflicting theories exist about them. In linguistics we are very far from the precision which can be attained in the physical sciences and even (though to a lesser degree) in the biological sciences. We can foresee an eclipse with a certain degree of exactitude; it is very difficult, although not at all impossible, to foresee changes in language with a certain amount of probability. This is, however, the case, and even to a much greater extent with the other social sciences, such as political history, sociology, law, and literature. Compared with these, the achievements of linguistics strike us as remarkable.

Sec. 2. *Two Elements of Language: Sound and Meaning.* Language is, as we have seen, the principal means by which men express themselves and communicate with each other; it is therefore symbolical; that is to say, it consists of two elements: the signifier (the material,

audible element of sound) and the signified (the thought, feeling, wish or idea we express or we want to express by means of the sounds). The first one remains within the realm of matter; it belongs essentially to the physical and physiological world and follows its rules; but the second one plunges deeply into the mysterious soul of man and reflects his life with all its desires, doubts, feelings, artistic cravings, and logical thought. It is obvious that, strictly speaking, only the second one can be of interest to psychologists, and therefore will be the only one with which we will deal in this article. It must be stressed, however, that this separation is to a certain extent an arbitrary one, for there is no language without a material (phonic) means of transmission, and at the same time there is no language without something to transmit or express. Words without meanings are not words, they are mere *flatus vocis*; nor does meaning alone make up a word. The two elements of language are closely connected, nay are absolutely inseparable, and it is evident that they react upon each other. The material, phonic shape of the word frequently modifies the meaning, and inversely the meaning sometimes modifies the word. But language consists of both: if there were no material way of transmitting thoughts or feelings through words and sentences, linguistics would be the same thing as psychology, and there would be no independent science of linguistics. It is precisely this duality which is the characteristic of linguistics and which distinguishes it from every other branch of study. (Cf. Dauzat, *Essai de méthode ling.*, p. 19; Hjelmslev, *Principes*, pp. 94 f.)

Sec. 3. *The Material Form of the Word Causes the Change.* The change of a word may be caused by its material form. I will give here some examples to illustrate this important point. Gilliéron has proved in a famous book that the 'bee' presents an enormous variety of different names in Northern France (*é, essaim, ruche, apier, avette, mouche, mouchette, mouche à miel, abeille, essette, jeune, alouette, oiselet, ues, uespa*, etc.), whereas in Southern France

we find everywhere the form *abelho* (from Latin *apicula*) with a few insignificant phonologic variations. The reason is, as Gilliéron brilliantly demonstrated, that the south of France had in the Latin epoch *apicula*, the north *apis*; the latter form, because of the phonologic decay characteristic of Northern France, became monosyllabic (*é*). Now, language tends to eliminate monosyllables, especially if they present few consonantic elements, because they are not clear enough, and can easily be drowned in the whole of the sentence, giving occasion for misunderstandings. But *apicula* in the south, although reduced to *abelho*, remained clear enough, and even penetrated finally into Northern France. *Abeille* (from *abelho*) is now the Parisian form, and has entered into the standard language.

In this case, as in many others studied by Gilliéron and other scholars, it is exclusively the material, phonic form, the body of the word which produced the change: the meaning of the word *apis* ('bee') had nothing to do with it. It is not because bees were more or less frequent in Northern France than elsewhere, or because they were more or less productive or important, or for any other reason of the kind, that the word *apis* was replaced; it is only because it was too short. The meaning was not the cause of the linguistic change. The same thing happened to many other words which have no connection whatsoever with the 'bee.' Of course the human mind also played a part in this process indirectly, because it became aware (more or less consciously) of the confusion, and selected other words; but the whole process started from the material fact that the word was too short, not from its signification.

The same is true for *homonymy*, which (as Gilliéron has shown beyond any possible doubt) has eliminated many words from the French language, and replaced them with others. Therefore it is only in those places where it would have coincided exactly in form with *molere* 'to grind' that *mulgere* 'to milk' disappeared (replaced by *traire* from the Latin *trahere* and other words); where there was no danger of confusion, the two words lived peacefully near each other (and so do the corresponding words, e.g., in German, in English, etc.). The same is true for 'cat' (*gattus*) and 'rooster' (*gallus*) in Gascony (where both would have become *gat*), for 'ear of corn' (Latin *spīca*) and 'thorn'

(*spīna*), for 'dog' (*canis*) and 'cat' (*cattus*) etc., in other regions of France; one or even both words disappeared, but only in those regions where the confusion existed; nor did it disappear in other languages, where conditions were different. In this case, as in others, language becomes a system, with its interior logic and development independent, to a certain extent, from the human will and human mind; that is, from its *meaning*.

Sec. 4. *The Meaning of the Word Causes the Change.* An example of the opposite phenomenon is the following. If we look at map No. 10 of the Linguistic Atlas of Italy (*Atlante italo-svizzero*), indicating the words meaning 'big' (French *grand*, German *gross*), we will immediately notice that, apart from Sardinia (which has forms representing Latin *magnus*), all regions have forms corresponding to Latin *grandis*, with only a few exceptions in Rhaetia and central Italy (*karšius*, *grosso*); it is a very uniform, monotonous map. But if we pass to map No. 39, showing forms meaning 'little' (French *petit*, German *klein*) we will find a vastly different picture with a great variety of forms. Sardinia has *minore*, *pičkoku*, *pittlu*, *pittikku*, etc.; Sicily, *piččiriddu*, *niku*, *piččittu*, etc.; Campania, *tsiku*, *piččulu*, *paččari*, etc.; Latium, *dzigo*, *ččuko*, *pičkukulu*; Tuscany, *piccolo*, *piccino*, *šikko*; Emilia, *cinc*, *ček*, *sney*, etc.; Venetia, *čeo*, *pičkoyo*, *péyčo*, *masa*, etc.; Piedmont, *čiz*, *pitodo*, *pš*, etc. Even more characteristic is the opposition between 'man' (maps Nos. 47, 181, 182) *uomo*, *uòmini*, and 'child' (*bambino*: maps Nos. 40, 42, 43) or *boy* (*ragazzo*: maps. Nos. 44, 45) or even 'young man' (*giovannotto*: map No. 46). While the words for 'man' constantly, without any exception, represent phonetically Latin *homō*, the words for 'child', 'boy,' and 'young man' present a tremendous variety, dozens of forms of different origin. The same holds true if we compare the various Romance languages with each other: Italian *uomo*, French *homme*, Spanish *hombre*, Portuguese *home* go back to the Latin *homō* (or to the accusative *hominem*); but Italian *bambino* (*putelo*, etc.), French *enfant*, Spanish *niño*, Portuguese *meninho*, *criança*, and Italian *ragazzo*, French *garçon*, etc. (cf. the Atlas ling. de la France), Spanish *muchacho*, Portuguese *rapaz* are of different (and in general recent) origin. Cf. likewise Italian *grande*, Spanish *grande*, French *grand*, but Italian *pic-*

colo (or *piccino*), French *petit*, Spanish *pequeño*, *pequeñito*.

Here it is obviously *not* the *form* of the words which has caused the change; there was nothing in the Latin words for 'little' (*parvūs*), 'child' (*puer*, accusative *puerum*), boy (*adulescens*) which should justify their elimination: they are not too short, they are not subject to any sort of confusion through homonymy: words of similar structure have not disappeared (cf. e.g., Italian *corvo*, Spanish *cuervo*, etc., from the Latin *corvūs*). It is obviously their *meaning* that provoked the crisis. Although in pure, dry logic 'big' is nothing but the opposite of 'little' (they are two opposite qualities of any object or being), in real life the two expressions are by no means directly comparable; while 'big' represents a rather prosaic, insignificant, objective, "neutral" quality, 'little' is charged with sentimental, affective, poetic and erotic values: it suggests grace, weakness; it arouses in our souls compassion, love, tenderness—feelings that are associated with women and children. The same is true, of course, for 'man' and 'child.' To call a woman twenty years old 'baby' is often a compliment; it is a ridiculous expression, if not an insult, when applied to a man of that age.

Language—we may therefore stress even now—does not follow dry, abstract, philosophical logic; it rather reflects the sentimental, artistic and emotive part of the soul. It can be interpreted through psychology, not through logic. It has its sources much more in the subconscious, irrational, childish and poetic section of our psyche, than in the logic, rational, conscious and philosophical one.

Sec. 5. *Popular Etymology*. Likewise, in the case of so-called popular etymology, the *meaning* reacts on the *form* or *phonic material* of the word. There is nothing wrong with the English word *asparagus*; it is a good word to indicate a certain eatable vegetable. But it is (as many other words, of course) a mere symbol, like a tag on the objects in a museum, or a number in a catalogue. It perfectly satisfies the need of a symbol for understanding between men; but the difficulty is that language is not only a means of communication of ideas and facts (as some linguists wrongly claim), it is (and even more so) an artistic means for the extrinsication of man's feelings, imagination and poetical fantasy, of his need of *expression*.

The word *asparagus*, logically satisfactory, does not satisfy the speaker's imagination: it is replaced, in some dialects, by *sparrow-grass*, which is logically much less satisfactory, since it is inexact (*asparagus* is not a *grass*, and *sparrows* do not usually eat it) and moreover apt to cause confusion (someone might confuse *asparagus* with some other kind of plant which *sparrows* usually eat, or believe it to be a grass). Still, despite these linguists, popular etymology—a purely artistic and emotive phenomenon—is extremely frequent (as Gilliéron has shown) and much more so than is usually admitted in linguistic manuals. These so-called *popular etymologies*, he said, frequently despised by "orthodox" scholars as *false*, because they disturb the regularity of "phonetic change," are in effect real, much more real, in a way, than the etymologies of our dictionaries, since they act and change the *form* and frequently also the *meaning* of words, a thing which the scholarly etymologies of our etymological dictionaries never do.

Other examples in English are *east-worm* or *easter-worm* for *eat-worm* (root of *eat*, cf. Latin *ēscā* from *edō*; the worm is used as *bait*) in the Ling. Atlas of New England (map. No. 236); *goose-berry* from *groze-berry* (*groze* comes from a French word akin to the modern French *groseille*); *man-drake* from *mandragora*; *bridegroom* was in Old English *brydguma*, where *-guma* is 'man,' Latin *homō*, etc. (I take some examples from Bloomfield, *Language*, p. 423); inversely the English *country-dance* became *contredanse* in French (which is an absurd formation, Vendryes remarks!); and there is no more sense in *lait d'anon* from Latin *laudanum*; likewise, Italian *pomi dei Mori* became in French *pommes d'amour* (whence English *love-apples*, German *Liebesapfel*) etc. (I take these examples from Vendryes, *Language*, p. 213.)

Sec. 6. *Is There a Connection between Sound and Meaning?* Obviously not, if we mean a *necessary* connection; nothing seems to be *necessary* in language, as is the case in any other human activity, such as art, literature, politics, etc. It is clear that if such a necessary connection existed, two consequences would inevitably result: first, language would never change; second, we would all speak the same language, since the same idea or feeling could be expressed only by one word, always the same. This is

evidently not the case. When the Englishman says *book* and the Italian says *libro*, or even better, when the Englishman says *one thousand* and the Italian says *mille*, they mean absolutely the same thing, without the shadow of a difference: still, although the meanings are identical, although the speakers have exactly the same idea in their minds, they express them by means of quite different words: the words *book* and *libro*, *thousand* and *mille* have absolutely nothing in common in form, and they never had, for they are of entirely different origin. They are two different tags attached to the same object, having no other function but to indicate the object in two different, yet quite equivalent ways. This is what linguists mean by the *arbitrary character of the linguistic sign*, that is, of the word (in its phonic aspect). It is as if by convention some men had agreed on some values of certain groups of sounds, and other men on other, quite different values. This is clearly shown, e.g., by the symbols called numerals: 100 is pronounced in different ways by all peoples in the world, yet when they pronounce the corresponding words, they intend to express exactly the same idea.

Sec. 7. *Onomatopoeia or Creation of Words by Imitation of Natural Sounds*. However, this idea of the arbitrary character of the sign, which is correct in general, cannot be accepted today with the same rigor as it was thirty years ago. Nothing is *absolute* or *rigorous* in language. There are at least two important reservations to make. The first one, known for a long time, is the so-called *onomatopoeia* or *direct imitation* of natural sounds by means of the phonic material of words: English *blab*, *splash*, *bubble*, *chink*, *clank*, *sizzle*, etc., are simple reproductions of the sounds produced by the objects or beings they represent, or the action of producing the sound. Certain words or actions where the sound is most characteristic are more frequently, or almost regularly, of onomatopoeic origin in all languages: so the bird *cuckoo*, German *Kuckuck*, Italian *cuculo*, Greek *κόκκυβς*, Old Church Slavonic *kykavica*, Sanskrit *koṭilās*, etc. (notice the absence of the sound-shift in Germanic, which points to a new creation in the Germanic languages); or English *whisper*, Danish *hviske*, Old Norse *kvisa*, German *flüster*, French *chuchoter*, Italian *sussurrare*. We would be led to think that we approach here the process of the creation of language itself;

could not all words have originated this way? This seems to be, however, at least for the present, a very daring hypothesis, for the percentage of words of sure onomatopoeic origin in all languages is (and always was, as far as we know) very small; they are limited to a few concepts, usually the same everywhere. Moreover, they seem to remain apart from other words, preserving frequently against all phonologic changes their particular onomatopoeic character; they rarely enter, so to say, into the great stream of language.

We can probably include in this same class *nursery forms* or *infantile words*, such as *baby*, *daddy*, *mommy*, *mama*, French *bébé*, *papa*, *maman*, *pipi*, Italian *bambino*, *mamma*, *babbo*, *tata*, *pappa*, *tutti*, *pupù*, Latin, *atta*, Turkish *Ata-türk*, etc. It is not surprising that they are found in similar forms all over the world.

Sec. 8. *Symbolic Value of Certain Sounds or Groups of Sounds*. The other reservation to be made to the general assertion of the *arbitrary character of the sign* is the fact, noticed only recently, that certain sounds are frequently (although never necessarily) associated with certain meanings, although no onomatopoeia whatever can be discovered. If we examine the Italian words for 'child' and 'little' on the maps of the Italian Linguistic Atlas, we will immediately notice that, although different from each other and not allowing any common etymology, they offer a certain resemblance: we frequently find groups like *pit-*, *pič-*, *pič-*, *čit-*, *čik-*, *nič-*, *čuk-*, *isik-*: the vowel is *-i-* (less frequently *-u-*), usually enclosed between two stops (or an affricate and a stop). They resemble each other, but the variations enter into no "phonetic rule" whatever and are not comparable with those of the majority of the other words (they do not present such "normal" variations as Tuscan *pelo*, Sardinian *pilu* or the like). The same can be frequently noticed in other languages: Latin *pitinnus*, *putillus*, *pusinnus*, *pisinnus*, French *petit*, Spanish *niño*, *chico*, *pequeño* (from something like *pikḱineus*). English *little*, *chick*, *kid*, *kitten*, *dinky*, *teeny-weeny*, *wee*, Romanian *mic*, Greek *μικρός*, etc. On the other hand, in the adjectives meaning 'big', 'fat', we frequently find the broad or deep vowels *a* or *o*: Latin *magnus* (preserved in Sardinian *mannu*), *grandis*, *crassus*, Italian *grande*, *gresso*, *grasso*, Spanish *grande*, *gordo*, French *grand*, *gros*, *gras*, German *groß*, Russian *bolšoj*, etc. The same is

frequently remarked in suffixes: Italian *-one*, *-otto* are augmentatives, but *-ino*, *-etto* (from *-itius*), *-uccio*, *-illu* (in dialects) are diminutives, as are Spanish *-ín* and *-ito* (which according to "phonetic rules" should be *-eto*).

This important problem has been investigated very little up to now; but if properly studied, it is apt to shed much light in the near future on many linguistic questions.

Sec. 9. *Poetical Harmony*. In this problem doubtless lies the secret of harmony in poetry. There is no doubt that in all great poetical creation there is a mysterious link between phonic form and meaning: this can easily be proved by substituting in any verse of Shakespeare, Shelley or Dante one word with a synonym of identical meaning, accent, and number of syllables, but of different phonic composition (vowels and consonants). Although it is difficult to say in every case why, we feel clearly that the beautiful verse of Dante:

non sonò sì terribilmente Orlando

expresses an epic, dramatic, warlike content (only consider whether these sounds could fit, e.g., a love-scene); likewise in the famous *terzina*

*Quale ne' plenilunii sereni
Trivia ride tra le ninfe eterne
Che dipingon lo ciel per tutti i seni . . .*

describing the purity and joy of a serene lunar night studded with stars, Dante has obviously sought a particular effect by the abundance of liquid consonants (*l, r, n*) and acute vowels (*i, u, e*; notice the almost total absence of *o*, the scarcity of *a*: 2 out of 33 full vowels). No person with a minimum of taste for poetry would hear a battle-cry or a funeral mourning in these verses, just as he would not hear an outburst of joy or a nuptial march in Verlaine's:

*Les sanglots longs
Des violons
De l'automne
Blessent mon coeur
D'une langue
Monotone.*

Or:

*Il pleure dans mon coeur
Comme il pleut sur la ville,
Quelle est cette langue
Qui pénètre mon coeur?*

It would be easy to multiply examples, and every person even slightly familiar with poetry will find many more.

Sec. 10. *Does Language Represent Society?* If language is a characteristic of the social activity of man, if linguistics is (as we said) a social science, it seems a natural conclusion that language must represent society, must reflect its ideas and feelings, and so on; the English language should therefore be the mirror of the English people, the Italian language, of the Italian people, and so on. This important question does not allow a simple and precise answer. Several considerations must be taken into account.

First of all, granted that language represents the culture of a people, it would be true that, e.g., English represents the culture of the English people, let us say in the twentieth century, only if the English had created *ex nihilo* their own language in this century. This is obviously not true; the English language of the twentieth century is nothing but the continuation and development, with a very few changes, of the English language of the nineteenth, and this in turn is the continuation of the language of the eighteenth, and so forth back to Germanic and Old French, etc. Therefore, modern English, if it does reflect any culture, must reflect not only and specifically the culture of the generation that is speaking it, but also the culture of all the generations that spoke it in the past, and whose respective cultures differed widely from that of our own time. In other words, language is a historical product, the result of an infinite series of historical changes, an organic accumulation of fossils of all times; it is a sort of a museum of antiquities of all ages, where many, even most things, seem to us, if we consider them linguistically, anachronistic and absurd in our time, just as the weapons and instruments we see in a museum. The English language is not more up-to-date than the English spelling; it is even much less so. There is no logical reason for plurals like *goose: geese*, or *mouse: mice* (cf. *house: houses*); and there is no logical reason in modern French for the feminine gender of *la lune* 'the moon' and the masculine gender of *le soleil* 'the sun'; this opposition had a meaning thousands of years ago, but it has none today: still it is deeply rooted in the French language (although it has almost disappeared from English) and, absurd as it is,

shows no sign of weakening. Tradition, an extremely strong factor in all social phenomena, is perhaps even stronger in language than elsewhere. It is the fundamental force in language.

Modern English or modern American are no more a creation of modern English and modern American culture than the classical Roman architecture of Pennsylvania Station in New York; that is, only to a very limited extent, since obviously another architectural style could have been chosen for the construction of that building.

In the first years of his life, the American or the Italian child learns his language from his elders, that is, he *imitates* it, and he does the best he can. All his efforts tend not towards differentiation, but towards assimilation; in other words, he does not choose his language; his language is imposed upon him, and during all his life society will vigilantly observe him and eliminate either by satire or by even direct compulsion (examinations in school, hindrances in his career, social boycott, etc.) the errors in his speech, that is, the infidelity to the traditional ancestral pattern of language. Under these conditions, it is not surprising that language changes so little. It is surprising that it changes at all.

Therefore, the possibility that the English language in the twentieth century may reflect the English culture of the same period has to suffer one limitation: that only the changes introduced during the twentieth century into the English of the nineteenth century can be considered as significant. However, other facts have to be taken into account.

Sec. 11. *The Three Aspects of Language.* English must not only be considered as a national institution; it is also a language in the universal sense of the word. All men speak, expressing thereby their feelings and thoughts, exactly as the English do, although by different means. In fact, every English speaker, as well as every Italian or every German speaker, has to be considered under three aspects. A man in general as opposed to animals is first of all a member of the human race; an Englishman has therefore many features, both biological and psychological, in common with the Japanese and the Zulus. He is in the second place an Englishman; that is, a member of the English community, in which he has lived and from which he has absorbed ideas, customs, behavior,

religion, poetry and so on. He is in the third place an individual man, with individual characteristics of his own, which make him a unique phenomenon and which distinguish him sharply from every other man, no matter how much he may have in common. The same is obviously true for language. We have, therefore, to distinguish three aspects of language (already indicated abstractly by De Saussure with the names *langage, langue, parole*):

a. *Language as a universal phenomenon.* It is a known fact that distant languages, apparently not related to each other, present similar grammatical or semantic phenomena. This is so true that many illustrious scholars consider it possible to discover some general rules and tendencies common to all languages of the world. This is what the great French scholar Meillet called *general linguistics* (*linguistique générale*). Following Meillet, and generally the French way of thinking in universal categories, the French school has concentrated on this aspect of linguistics, followed especially by the Danes. This will be examined in the following pages (Secs. 12 ff.).

b. *Language as a national phenomenon.* Language, with all limitations as stated above, doubtless reflects to a certain extent the culture and psyche (way of thinking and acting) of a certain people: the French language contains the accumulated historical experience of the French people, the German, of the German people, and so on. Although some exaggerations and technical mistakes have been committed in this study, there is no doubt that the tendency to study this aspect of language is not only permissible, but sound, and deserves every encouragement. Again it is probably not by chance that Germany, the country where Romanticism and the nationalistic movement was born, has also been the cradle of this method of investigation: Vossler, Spitzer, Lerch are among its most illustrious representatives. The whole movement began, however, with the Italian philosopher B. Croce. (See on this subject the following paragraphs.)

c. *Language as an individual phenomenon.* But language is also something which pertains to the individual man: no man speaks or writes exactly as the other one does. In his pronunciation, in the pitch of his voice, in his choice of words and sentences, in a word, in his *style* he differs from every other speaker and at the

same time reveals some physiological or psychological characteristics of his own, just as he does in his every act, even the most insignificant. If we know someone even to a very limited degree, we can recognize without difficulty a text written by that person. We may have difficulty sometimes in saying why we attribute such a letter, saying, or expression to Charles, Dick or James, but the fact remains that we do recognize his way of speaking or writing as surely as we recognize his face and sometimes even more. This is even more true in the case of an artist, whose style is of course more characteristic, more personal, precisely because art is nothing else but the strong expression of a strongly individualistic and independent personality. Nobody will confuse a page of Bernard Shaw and of Oscar Wilde, although they are contemporaries and write a perfectly correct English. This aspect of linguistics has been until recently almost entirely neglected, a fact which is deplorable, because, after all, all linguistic innovations are of individual origin, and the only concrete and real fact that we can study in linguistics is the *individual speaker*. We do not speak in chorus, and a concept such as *the English language* is already to a certain extent an abstraction, viz., a generalization drawn from the common features of all English speakers, disregarding the inevitable individual aberrations of each speaker from the abstract norm: that is, the individual, artistic, and imaginative element of each speaker—the gist itself of life.

It is not at all surprising that in Italy, that land of art, of Humanism, of the Renaissance, of Vico's philosophy, which asserted the personality of the individual thinker and creator against any superior force, the land where, as it has been said, "the plant that is man grows stronger than anywhere else," the study of this important aspect of language should have originated. The great Italian scholar Bertoni, a follower of Croce's idealistic philosophy, and some of his disciples, have written some essays on the language of several authors which should be models for a series of further studies in other countries.

Sec. 12. *Language as a Universal Phenomenon*. The attempts to write what is called a general semantic grammar for all languages (that is, the elaboration of general semantic categories) on which several distinguished

French, Czech, Russian, and Danish scholars have worked in recent years with very interesting results, have not yet reached a stage suitable for presentation in a relatively popular article as this wants to be. But there is another point on which many well-known linguists agree (I will mention here among the recent ones the names of Wackernagel, Meillet, Vendryes, Cuny, Lévy-Bruhl, Jespersen, Sommerfelt, R. Jakobson, Brøndal, Sapir, Sturtevant): all the languages of the world seem to show certain trends, to follow the line of a certain evolution; they all seem to pass through certain stages of development, just as humanity passes or passed through the stone-age, the bronze-age, the iron-age, etc., and showed some other common trends toward modern civilization. And just as in the case of human anthropology some tribes are even today culturally and psychologically on the level of the stone-age or the bronze-age, which we left behind us thousands of years ago, so in the case of language some living primitive tribes have preserved a more or less primitive type of language, which does not show the changes which other languages of more cultured people now show, or once showed, and have left behind them for a long time. In other words, the trend (as far as we can see in the languages whose history we know) is $A > B > C > D$; but some languages have remained in A or B, and show no trace of further developments. By no means do they constitute therefore an argument against what we may call the evolutionistic theory.

Sec. 13. *Examples of General Linguistic Trends*. Some examples of such *general linguistic trends* are the following:

- (1) Loss of the dual number in verbs, nouns, pronouns (in this order).
- (2) Creation of the definite article (usually built out of a demonstrative pronoun) and of the indefinite article (out of the numeral 'one').
- (3) Loss or weakening of the verbal aspect (as exemplified by the Slavic languages) and introduction of tenses as the basis of the verbal system.
- (4) The creation of a passive in the verb.
- (5) The elimination of gender.
- (6) The elimination of the nominal and verbal flexion.
- (7) The elimination (through analogy) of irregular forms, especially of what is

called very improperly suppletion (the type *ferō tulī, nūn rōboris*, etc.).

- (8) The transition from a synthetic to an analytic type of grammar (*dicō > I say, lupis > to the wolves, uideō > I have seen, uiderem > I would see*, etc.).
- (9) The trend from certain sounds or systems of sounds to others.
- (10) The progressive shortening of words, especially through the loss of the endings, eventually resulting in a monosyllabic structure.
- (11) The increase of abstraction in the lexicological material.

These phenomena (and several others which could easily be pointed out) are produced so slowly, in such a roundabout, hesitant, and often contradictory manner, that their action can frequently be recognized only when we compare two stages of the same language hundreds or even thousands of years apart; and this of course is possible only in very few cases (Greek, Latin, Iranian, Sanskrit, Chinese, and some Semitic and Hamitic languages).

Of course, discussion and doubts may arise on some of the phenomena mentioned above; however, so many and such authoritative linguists agree on the general principle of the trend (and this is what really matters here) that the question deserves to be examined by psychologists, for whom it is of the utmost importance.

Sec. 14. *Psychological Explanation of the General Linguistic Trends.* To observe facts is one thing; to explain them, another. While many linguists (perhaps a great majority) admit the general trends indicated in the preceding section, some of them may not agree on the explanation, and will merely limit themselves to observe things, without any attempt to an interpretation. This is, however, not difficult to find, and has been already proposed by several of the scholars mentioned above. It follows essentially the lines anticipated by the great philosopher of history, Giambattista Vico, whose work, almost entirely neglected until recent years, contains in germ the elements for the solution of most great problems concerning man—art, literature, philosophy, law, customs, etc. The explanation is, in short, this: During the evolution of humanity from primitive forms of life to modern civilization, the way of thinking of man—that is, his mental categories—has

changed not less than his material way of living—nay, we can say that his material way of living has changed precisely because his way of thinking has (without denying, by this, that to a certain extent his material way of living has reacted upon his mind, modifying and especially accelerating his mental evolution). Concepts, thoughts, reasoning which are familiar and even obvious and trite to us, the heirs of thousands of years of more or less logical thinking, were not so to our ancestors of the palaeolithic age, nor to contemporary savage tribes. The primitive man lives in a mystic, magic, emotive, irrational atmosphere, full of religious interdictions, fears, and superstitions. This whole conception of life, of causality, of things is highly subjective and entirely different from our own. Just as for the child, for him nature is alive, populated by strange and evil monsters, by thousands of different gods, nymphs, spirits, goblins, which have to be honored, feared, and placated, which constantly threaten his life and security if not properly treated with the elaborated ceremonial of magic rites. A stone is a stone for us, a dead object, a thing, a compound of certain chemical substances; it is a force, a daemon to the primitive, it is endowed with terrible, mysterious powers (and this belief, e.g., subsisted in part throughout the Middle Ages). The trend of civilization is on the contrary towards an objective, factual, rational, logic mentality. This does not mean at all that we are always perfectly logical, that we reason well; but even when we fail to do so (and we frequently do) at least we try or pretend to reason according to certain logical standards, which the primitive man did not possess, or at least possessed in a much smaller degree.

It is of course obvious (and really need not be said) that this opposition is not absolute, as no human fact is; and that some rational element will always be found among savage tribes, even among the most primitive, while on the other hand we know only too well that elements of primitive thinking survive everywhere in civilized societies, and that they still lie deep in the soul of every man.

The child's mentality will help us in many cases to understand the primitive man, since it is very likely that, just as the focus goes through the whole evolution of the species, the mind of the child goes in a few years through

all the long and painful paths of the mental development of mankind (and perhaps not only of mankind) through the ages.

Sec. 15. *Aspect and Time in the Verbal System*. In most languages of the world verbs have no *tenses*, but only *aspects*. This corresponds to the mentality of the primitive man, interested very much in movement, in the way the action is produced, and in its result; that is, in the aspect (unique, iterative, perfective, imperfective, punctual, linear, durative, intensive, terminative, ingressive, etc.). It is a well-known fact that savages have much finer and more delicate senses than we have, that they can perceive thousands of sounds, smells, colors, objects which escape us entirely. They are nearer to nature and their life is concentrated on exterior objects and sensations, on which their difficult daily life is based. The same is true, of course, for our ancestors of Europe. Solomon Reinach writes the following remarks on the palaeolithic art of the reindeer hunters:

"Finally—and this is perhaps the most extraordinary detail of all—the artist of the reindeer age is in love with life and movement; he likes to represent his animals in lively and picturesque attitudes; he seizes and reproduces their movements with extraordinary precision. . . .

The masterpiece of this phase of art is perhaps the group of stags engraved on an antler discovered in the cave of Lorthet (Hautes Pyrénées). First we see the hind feet of a stag which is galloping away. Next comes another galloping stag, in an attitude first revealed to us in modern times by instantaneous photography as applied to the analysis of rapid movement. An artist of our own day, Aimé Morot, first made use of the knowledge gleaned from photographs, and reproduced this action in his horses. It was unknown to all artists of intermediate ages."¹

Time, on the contrary, a very abstract category, is almost absent in the mind of the primitive. He cannot read or write, nor use calendars; he does not know his own age or that of his wife or children, nor does he care to know. All his interests are in the present, with all its problems so complex to him. The past he forgets quickly, the future he cares little about. Time-determinations—even outside of the ver-

bal system—are rare or absent in primitive languages. It is also a well-known fact that the *time-adverbs and prepositions* in all languages—so far as an etymology can be found—were originally *spatial expressions*: space is psychologically a much more concrete mental category than time, since several objects appear in space contemporaneously and can be perceived by our senses and compared. This is not true of time.

The most difficult tense to produce is, of course, the future. Few languages have a true future tense, although many will somehow express a future event with the help of adverbs such as *tomorrow*, *next month*, etc. Future is the last tense to appear and only after a long and difficult struggle. Usually languages help out by means of periphrases with verbs like *I will* or *I shall* or *I can*, a proof that what was originally meant was a *wish* or a *duty*, or a physical or mental *capacity*, not a real, *prospective* future. To foresee, prepare, anyhow consider objectively—without sentimental interferences—future events is in effect one of the most difficult tasks of human mind, much more so than to remember the past (a fact which clearly reflects in grammar.) It is practically impossible to reconstruct an Indo-European future; Slavic languages have even today no clear formation for the future; Gothic had no future; modern German makes no great use of its heavy construction with *werden* (a relatively recent innovation); even English, otherwise a very modern language, has not yet developed a true, unequivocal future, like French *je ferai* or Italian *farò*, as proved by the famous joke of the drowning Irishman who cries: "I will drown and nobody shall save me"—a joke which would be impossible in Italian. It is also probable that the loss of the Latin future in the Romance languages (which later reconstructed a new future with *habere*, originally of the *shall* type) is due to the ruin of a philosophical, intellectual civilization as the Greco-Roman was and its replacement with an emotional, fantastic, mystic type of culture, but of a definitely lower intellectual standard. Vossler's remarks on the future in general are anyhow excellent (*The Spirit of Language in Civilization*, New York, 1932, p. 61): "But [in vulgar Latin] the whole temporal conception of the future was weak and it broke down. There is hardly a language in which it is regularly used by the

¹ *Apollo*, English translation, New York and London, 1924, pp. 5 f.

common people. The concept of the future, like the prophet in his own land [?], is usually neglected, or in some way misused and obscured by colloquial speech. For the ordinary man, attitude towards things is always that of willing, wishing, hoping, and fearing, rather than that of imagination [?], thought or knowledge. Probably the surest measure of the extent and depth of our education is the degree of calm and self-possession that we preserve in view of the future. Continuous collectedness and self-possession—in short, a philosophical temperament and attitude of mind—are needed if the temporal outlook on the future is not to deviate into the modal spheres of fear and hope, of the wish, and of the uncertainty."

That children have likewise very vague conceptions of time, and are not interested in the matter, is also a well-known observation.

Sec. 16. *The Origin of Gender.* It would be easy to show how, in the same way, several other of the general trends mentioned above (such as the loss of inflection, the creation of the article, the loss of the dual) can be explained; but such a demonstration would surpass the limits allotted to this subject by this encyclopedia. I will treat here only the disappearance of gender, because of its special interest from the point of view of psychology. It is a well-known fact that in modern languages gender is in most cases an absurdity from the contemporary point of view. There is no reason why, in modern French, 'the nose' (*le nez*), 'the field' (*le champ*), and 'the sun' (*le soleil*) should be masculine, but 'the table' (*la table*), 'the mouth' (*la bouche*) and 'the moon' (*la lune*) should be feminine. In other cases—when human beings or animals are concerned—the thing seems, within certain limits, justified. Here genders correspond (although by no means perfectly) to the sexual opposition of male and female. 'The boy' and 'the bull' are masculine (*le garçon*, *le taureau*), but 'the girl' and 'the cow' are feminine (*la jeune fille*, *la vache*), although even in this domain some incongruities might be found (Italian *la guida* is generally a man; *la lepre* 'the hare,' *la tigre* 'the tiger' are always feminine, but *il gatto* 'the cat,' *il leone* 'the lion' are always masculine unless specification is needed). There is no explanation from the point of view of Italian and French; these "absurdities" go back to Latin, where *campus*, *nāsus*, *sōl* were mascu-

lines, but *bucca*, *lūna*, *tabula* were feminine; and Latin itself offers no clear explanation. We have to go further back. The right solution of this strange phenomenon was already guessed by Humboldt and Herder, and then developed by Adelung, Grimm (*Deutsche Gr.*, 3, 345 ff.), Pott and recently by Jacob Wackernagel and by the great French scholar Antoine Meillet. This explanation lies deep in the mentality of our Indo-European ancestors. Gender was due originally to the personification (or divinisation, which is a sort of personification) of inanimate objects (stone, water) or phenomena (fire, thunder, rain, day, etc.) in the mind of the primitive man. Just as the child hits in revenge the table or the wall that hurt him while he was playing, so does the primitive man attribute soul and life and will to objects or plants; Greek and Roman mythology still abounds with nymphs and gods of springs, mountains, rivers, trees, etc., which are nothing but personifications; long stories are told about their exploits and loves, which constitute one of the main themes of classical poetry. The *sun* and the *moon* were gods, therefore living beings endowed with *sex*, and so were *heaven* and *earth*, frequently united in mystic marriage (as e.g. in Hesiod). That is why they are of opposite sexes. It will be noticed that although their sexes may interchange, the opposition remains: if 'the moon' is masculine (German *der Mond*, Lithuanian *mėnėsis* or *mėnuo*), then 'the sun' is feminine (German *die Sonne*, Lithuanian *saulė*); but when 'the moon' is feminine (Latin *lūna*, Greek *σελήνη* or *μήνη*), then 'the sun' is masculine (Latin *sōl*, Greek *ἥλιος*). In Lithuanian and Latvian folk-songs, 'the moon' (masculine) is the husband of 'the sun' (feminine). Latin *aqua* (feminine) and *ignis* (masculine) are likewise a close couple (cf., e.g., the age-old formula *aquā et igni interdīcere*). Slav has also *ogni* (masculine) and *voda* (feminine); but in Lithuanian, where *ugnīs* is feminine *vanduo* is masculine! Now the worship of springs and rivers (of moving waters) is well known in antiquity. The waters and the fire (another moving element) are important divinities in the Avesta and in the Vedas. *Agnis* (the same word as *ignis*) is the most important god. It can be seen clearly that, when we do not find in one language (German, French or Latin) the answer to our question, we usually find it in an older stage, through comparison and re-

construction, provided we try to understand the mentality of people who were different from what we are now.

'The day' and 'the night,' so easy to oppose to each other, also make a couple: Latin *diēs* is masculine (cf. the god *Diēs-piter, Iuppiter*, Greek *Ζεὺς πατήρ*, Sanskrit *Dyaús pitá*), but *nox* is feminine (German *der Tag, die Nacht*; Russian *djen, masculine, noc, feminine*).

It will be noticed that frequently the gender remains, although the name itself changes. The Latin *lūna* is a different stem from the Greek *σελήνη* or *μήνη*, but they are all feminine; German *der Tag* is a different word from the Latin *diēs* or Russian *djen*, but they are all masculine, and so German *Himmel*, Greek *οὐρανός* as opposed to *Erde*, Greek *γῆ, γαῖα*. The personification and consequent sexualization is so strong that it survives even the loss of the word. Another excellent example is the word for 'hand,' which is feminine in most Indo-European languages, although represented by quite different stems: Latin *manus*, Greek *χείρ*, German *die Hand*, Lithuanian *ranká*, Russian *рукá*, etc. Sometimes the masculine is found, as in the Tocharian A *tsar*, Avestan *gav-* (the daëvic word), *zasta-* (the ahuric word), Sanskrit *hástas*; but never the neuter. Likewise, the 'finger' is almost always masculine, although its stem changes everywhere. 'Hand,' 'finger,' 'foot,' 'tooth,' 'tongue' are moving, living parts of the body which cannot be conceived as objects. Cf. on the other hand, Latin *oss* 'bone,' Greek *ὀστέον*, Sanskrit *ásthi*; Latin *genū* 'knee,' Greek *γόνυ*, German *das Knie*, Sanskrit *jannu*; Latin *iecur* 'liver,' Greek *ἥπαρ*, etc.; and also *das Herz, das Bein*, Latin *crūs* n., *cor* n., *corpus* n., Greek *τὸ κῆρ, τὸ σῶμα*, *τὸ σκέλος*; 'head,' 'mouth,' 'eye,' 'ear' vary. Nor is it difficult to understand, in my opinion, why 'the tooth' (a strong, hard, fighting, penetrating element) should be masculine, 'the tongue,' weak and soft, generally feminine: Latin *lingua*, German *die Zunge*, Greek *γλῶσσα*, Avestan *hizvā*, Sanskrit *jihva*; masculine in Avestan *hizit*, Russian *язы́к*, Lithuanian *liežuvis*; the neuter is never found.

'The wind,' 'the storm,' 'the thunder' are never conceived as objects, as inanimate things. They are never neutral; they are powerful, active, dangerous forces: 'the wind' is masculine (Latin *uentus*, German *der Wind*, Greek *ἄνεμος*, Russian *вѣ́тер*, etc., and so 'thunder'

in Latin (*tonitruius*), German (*der Donner*), Russian (*гром*); while 'the storm,' perhaps conceived as a larger, enveloping force, is frequently feminine: Latin *tempestūs, procella*, Greek *ἄελλα*, etc. *Wind* and *thunder* are gods, or are represented by gods, in the mythology of several Indo-European nations. The Latin *salūs* (feminine) corresponds etymologically to the Avestan goddess *Haurvatāt*.

Meillet has likewise discovered that 'sleep' and 'dream' are active, living forces which impose themselves upon man: Latin *somnus*, Greek *ὕπνος*, Russian *сон*, German *der Schlaf*; Greek *ὄνειρος*; German *der Traum*, etc. Death, the old man with the sickle, who "carries us away," is feminine (Latin *mors*, Russian *смѣ́рт*, etc.) or masculine (Greek *θάνατος*, German *der Tod*), never neuter.

Abstract nouns were also conceived as divine powers, dominating, impelling, and attracting man; they are very seldom neuters: Latin *amor, terror, metus, libidō, cupidō* (also a god!), German *die Liebe, die Furcht, der Wunsch*, Greek *ὁ φόβος, ὁ Δεῖμος* (both personified in Homer). They are generally feminine, as the Greek nouns in *-ος* (*δόσις*, etc.), *-της*, the Latin in *-tūs, -tās, -tūdō, -tiō*, the German in *-ung, -heit, -schaft, -nis*, the Russian in *-отá*, etc. We see here a step of the primitive mind in its painful striving toward the formation of abstracts.

Sexual imagination surely played an important part in the personification, which means essentially sexualization of objects and events. We have seen, above, the examples of 'tooth' and 'tongue.' The *hand* (and so the *palm*), Meillet remarks, is usually feminine, because it receives; the *foot* is usually masculine for opposite reasons. It is slender and long and enters into the road, which is frequently feminine (Latin, *uía*, Greek *ἡ ὁδός, ἡ ἀγρῶτός*, French *la rue*, Italian *la strada*, German *die Strasse*). The finger is almost always masculine. In Latin the names of trees (beginning with the tree itself, *arbor*) are feminine because they are productive creatures, whereas their products, the fruits, are objects and therefore neuters: *mālus, pirus*, feminine; *pirum, mālum*, neuter. Here, as usual, Latin preserves very old Indo-European habits. The tree was a living creature for primitive Indo-Europeans. It is called in Sanskrit *pāda-pas*—"the one who drinks through his or the foot"—and 'the root' is in Sanskrit *mūlam* (neuter),

which is obviously the same word as the German *das Maul*, 'the muzzle.'

The comparison, or, rather, the identification of the tree with the human being has remained deep in our souls for thousands of years. Horace has *redeunt iam gramina campis arboribusque comae*; Virgil incorporates Polydorus into a myrtle tree; and Dante in his *Canto of the Suicides*, Aristo in the description of Alcina's island gave to his fancy even more wonderful developments; and even in the twentieth century, a man educated in the most modern nation of the world, Joyce Kilmer (1886-1918), wrote the beautiful little poem that every American schoolboy still enjoys:

I think that I shall never see
A poem lovely as a tree.
A tree whose hungry mouth is prest
Against the earth's sweet flowing breast;
A tree that looks at God all day
And lifts her leafy arms to pray;
A tree that may in summer wear
A nest of robins in her hair;
Upon whose bosom snow has lain;
Who intimately lives with rain.
Poems are made by fools like me,
But only God can make a tree.

The tree's *hungry mouth* in Kilmer's poem is, in my opinion, the one decisive argument in favor of the etymology of German *Maul*.

Gender distinction becomes almost useless in a civilized society, where this primitive way of thinking slowly disappears and is only preserved to a limited extent in poetry and in rhetorical speeches; it is no wonder that several modern Indo-European languages are dropping it or have already dropped it (Armenian, English, Danish, etc.); it is in most cases, as we have pointed out before, a useless fossil. Even in the cases where it corresponds to the reality of sex (*le garçon, la femme*) it can frequently be dispensed with without inconvenience. Everybody knows that a boy is a male and a girl a female, without any gender distinction. English and Armenian are not less clear, from this point of view, than Greek or French. In the few cases where a distinction would be welcome, it is easily supplied by other means: a *tom-cat*, a *lady-guest*, a *male goat*, a *girl-friend*, a *she-devil*, a *man-servant*, etc.

However, genders have not entirely disappeared in modern English. They remain in the

pronouns (*he, she, it; who, what*) and show thereby that they are latent in the nouns, too. (*There was a girl: she was sleeping; there was a boy: he was sleeping; there was a house: it was open.*) But what is even more interesting, gender, although reduced today to the extent that it is, still retains in two important categories its primitive personifying quality: nations and ships are feminine; that is, they are referred to with feminine pronouns: *England is a great nation: she will never die; the Japanese battleship Yamato was sunk yesterday: she was the pride of the Japanese Navy*. The personification is quite clear. Nations are usually conceived as female creatures (in paintings, monuments, etc.), and so are ships, which were and still are animated beings, christened at their birth, possessing a definite individuality, of which the captain and the sailors speak with affection, pride, and love, with which they live and often die. Until recently they were also given names of women (*Mary, Elizabeth*, etc.) and frequently had feminine figures on their prows. "The *Liner* she's a lady, an' she never looks or 'ceeds," wrote Kipling.

Sexualization, that is, personification, does not always go as far as divinization. There are, as we have seen, many intermediary degrees. Sometimes it reaches only a stage which we with modern feelings would call little more than a comparison. In Indo-European and in the Romance languages even yet, as well as in Semitic, the feminine represents frequently, with respect to the masculine, either a collective idea, or something larger, or simply a plural. The famous German scholar Johannes Schmidt has proved beyond any possible doubt in his book *Die Pluralbildungen der indogermanischen Neutra* (Weimar, 1889) that the Indo-European neuter plural in *-a* (*opus, opera; epulum, epula; mendum, menda; iugum, iuga*) is nothing but an old feminine collective. We still have *epula, opera, menda, rāpa, arua, labia, lāmenta*, etc., and, even if some words are new, the type is surely very old. This is obviously the reason why the Greek neuter plural takes a singular verb and why Latin so frequently uses *ōra, guttura, colla*, etc., with the singular meanings. We understand perfectly how some nouns already in Indo-European had two plurals, one "individualizing" (Latin *loci, ioci*; Greek *οἶτοι, μῆφοι*, Russian *вѣлосы*, etc.), one collective (Latin *loca, ioca*, Greek *οἷα, μῆγα*, Russian *вѣлосѣ*,

etc.). In Italian and Romanian this type has persisted and even evolved further (*il frutto*, plural *i frutti* and collective *le frutta*; *l'osso*, plural *gli ossi* and collective *le ossa*; *il muro*, plural *i muri* and collective *le mura* [della città]; *il sacco*, *i sacchi*, *le sacca*, etc.). And a characteristic fact which proves that there is very definitely a sexual conception attached to this collective in *-a* is that it has reverted to a feminine: *il muro* like *il lupo*, but *le belle mura* like *le belle donne* (with the feminine adjective and pronoun). Moreover, we frequently find in the Romance languages a feminine in *-a*, indicating an object larger, or more comprehensive, or more open than the corresponding masculine in *-o*: Italian *la gamba*, *il garbo*; *la sacca*, *il sacco*; *la secchia*, *il secchio*; *la buca*, *il buco*; *la pozza*, *il pozzo*; *la spilla*, *lo spillo*; *la famiglia*, *il famiglia*; *la cosa*, *il cosa*; *la capanna*, *il capanno*, etc. Spanish *la huerta*, *el huerto*; *la saya*, *el sayo*; *la bicha*, *el bicho*; *la campa*, *el campo*; *la cepa*, *el cepo*; *la ceja*, *el cejo*; *la bolsa*, *el bolso*; *la cordera*, *el cordero*, etc., etc. Leo Spitzer, in *Revista de Filología Hispánica*, 3, 1941, pp. 362 ff., asserts that the feminine is bigger than the masculine because it "embraces" and "envelops" it, because the masculine "penetrates" into it; and no unprejudiced scholar, after studying the material presented in his article, can deny that on the main point Spitzer is right.

Sometimes, of course, the (real or supposed) character of an animal can decide the sex, that is, the gender of the noun: the strong, rapacious and cruel *wolf* is always masculine in the Indo-European languages (cf. the metaphoric meaning of the word in American slang!), whereas the weak, sly and cautious *fox* is frequently feminine. The *lion* is always masculine, the *butterfly* often feminine.

Of course, in the case of gender, as in language in general, the form has sometimes reacted on the meaning. Without going as far as Brugmann goes, we can very well admit that Old High German *namo*, *samo*, which were originally neuter (cf. Greek *ὄνομα*, Latin *nōmen*, *sēmen*, Sanskrit *nama*, Russian *imja*, *sēmja*, etc.), became masculines because of their ending, which recalled masculines like *scīmo*, Gothic *skēima*, and that Greek *τὸ λόγος* became *ἡ λόγος*, *τῆς λόγος* by analogy of the feminines in *-ā* like *σπορά*, *δορά*. It is also very likely because of their ending that Latin *populus*,

laurus, *ficus*, *cupressus*, and the other tree names became masculine in Italian (*il pioppo*, *l'alloro*, *il fico*, *il cipresso*, etc.). Here the weakening of the ancient sexual conception of the tree as a productive female perhaps made way for the change; but this fact alone obviously could never have changed the gender of these nouns.

Personification of inanimate things or phenomena doubtless played and still plays a very important role in language. Here is another example. Indo-European certainly possessed, and most Indo-European languages still possess, an abundant class of so-called "imperative" compounds, where the first element is a verb in the second singular imperative, and the second usually a noun (indicating the object of the verb): cf., e.g., Μενέλαος, Ἀγέλαος, ἀρχέ-κακος, ἐχέ-φρων, ἐχε-νήϊς, ἀρχέ-γονος, ἀρχέ-τυπος, Φερέ-νιος, φερέ-καρπος, δακέ-θυμος, φερέ-οις, ταλα-πενθήϊς, Τληπόλεμος, τέλη-θυμος, ἐλ-ελ-χθών, Sanskrit *Trasā-dasyus*, *radā-vasus*, *jahi-stambhas*, *ussahi-sodas*, *sthā-rasmā*, *śtaddhā-devas*, Avestan *xs'aya-ars'an-*, *fraspā-yaoxdtra*, *nisā-snaiois'*, *frazā-baodanh-*, Latin *exerci-pēs*, *Cēdō-ateram*, Old Church Slavonic *Daždī-bogŭ*, *Stri-bogŭ*, Czech *Vladi-voj*, Spanish *lava-platos*, *perdonavidas*, *rasca-cielos*, *caga-tinta*, *caga-aceite*, *cagarrropa*, *mata-moros*, *saca-corchos*, *salta-montes*, Russian *Vladi-mir*, *Vladi-vostok*, Italian *reggi-petto*, *rompi-tasche*, *Bevi-lacqua*, *rompi-scàtole*, *rompi-collo*, *Vinci-guerra*, *Scaccia-pensieri*, *batticuore*, *casca-morto*, *attacca-panni*, *attacca-bottoni*, *cava-tappi*, *guarda-roba*, *ammazza-sette*, *gratta-cielo*, *sali-scendi*, *tergi-cristallo*, *non-ti-scordardi-me*, *gratta-schiena*, *porta-lèttre*, *porta-pacchi*, *lava-piatti*, *porta-sigarette*, *porta-cènere*, *spaventapasseri*, *rompi-capo*, *gratta-capo*, *Frangi-pane*, *frangi-flutti*, *Schifa-lacqua*, *porta-bandiera*, *parafango*, *rendi-conto*, *crepa-cuore*, *schiaaccia-noci*, *accendi-sigari*, French *Boileau*, *Boi-levin*, *casse-tête*, *passe-partout*, *casse-cou*, *brise-lame*, *pissenlit*, *passe-temps*, *coupe-gorge*, *garde-manger*, *essuie-mains*, *fai-néant*, *porte-manteau*, *gratte-ciel*, German *Tauge-nichts*, *Habe-nichts*, *Sprich-wort*, *Stell-dich-ein*, *Vergiss-mein-nicht*, *Thu-dich-um*, *Habe-recht*, *Schreck-den-gast*, *Schreck-den-feind*, *Rühr-mich-nicht-an*, *Trau-gott*, English *break-fast*, *break-water*, *break-neck*, *break-vows*, *cut-paper*, *cut-purse*, *cut-throat*, *cut-water*, *dare-devil*, *pick-pocket*, *Do-little*, *Drink-water*, *Shake-lady*, *Shake-lance*, *Shake-spear*, etc. Some scholars (e.g., Osthoff and Jacobi) have asserted, it is true, that the first element of these com-

pounds is not an imperative, but a "pure verbal stem." This is, however, flatly contradicted by such forms as the Greek Ἀρχέ-κακος, χαρε-κακία, Χαρε-στρατος, Χαρε-δημος, Φαινέ-λας, φερέ-οικος (we would expect -ο- at the end of the first element of an Indo-European compound), Sanskrit *jahi-stambha-s*, *ujjahi-joda-s*, Slav *Stri-bogŭ*, *Daždŭ-bogŭ*, Italian *non-tiscordar-di-me*, *accendi-sigari*, *rompi-collo*, *reggi-petto*, *sali-scendi*, *batti-panni*, *Bevi-lacqua*, *rendi-conto* (the "pure stem" would be *accende-rende*, etc.), Spanish *haz-me-rreír*, *ten-t-em-pié*, *ten-t-en-el-aire*, *ten-te-mozo*, French *rendez-vous*, *chassez-croisez*, German *Vergiss-mein-nicht*, *Thu-dich-um*, etc., are forms which evidently have an imperative as the first element.

Now, as can easily be seen, many of these forms do not indicate *persons*, but *objects*, *concepts* or *feelings*; they are obviously personifications, and are addressed with a sort of vocative: *break (the) water! break (the) fast!* Cf., e.g., Greek δακέ-θυμος (ἄντ), φερέ-πονος (ἀνταλία), φερέγγυος (ἀμην), ἐχε-πενκές (βέλός), Russian *Vladi-vostók*, Italian *reggi-petto*, *attacca-panni*, *taglia- carte*, *accendi-sigaro*, *porta-sigarette*, *rompi-capo*, *gratta-capo*, *crepacuore*, *schiaaccia-noci*, French *casse-tête*, *cure-dents*, *brise-lame*, *coupe-papier*, *essuie-mains*, *passe-temps*, English *break-fast*, *cut-paper*, *break-water*, etc.

It is also very likely that—as some scholars claim—a *divine force*, an *agent*, is hidden in the pronoun of the so-called "impersonal" verbs, such as: English *it rains*, *it snows*, French *il pleut*, *il neige*, German *es regnet*, *es schneit*, *es gießt*, *es schüttet*, etc. Cf., e.g., Latin *Iūpiter fulgurat*, *Iūpiter tonāns*, *Ioue fulgente*, Greek *Zeús ũe*, ἀστράπτει, ἑβρόντησε, ὕσαν ὠφίλε *Zeú ō theós ēseisen*, etc. These verbs even take an object in the accusative: Greek *ũei χωρσόν*, Latin *pluit sanguinem*, German *es regnet Steine*. The Western Romance languages use even, for similar sentences, the typical verb of action, *facere*: Italian *fa freddo*, *fa caldo*, French *il fait froid*, *il fait chaud*, *il fait du vent* (cf. *il y a du pain*). We are still animistic in our modern culture when we say *the wind shakes the house*, *the lightning killed a man*, French *le tonnerre gronde*, *le vent chasse les nuages*, Spanish *la tempestad ruge*. Even the "impersonals" indicating sentiments or feeling, such as Latin *mē taedet*, *mē miseret*, *mē paenitet*, *mē piget*, *mē pudet*, German *es gelüstet mich*, *es gemahnt*

mich, *es graut mich*, *es schaudert mich*, where again the accusative of the pronoun shows clearly that an active, unknown, mysterious force is hidden behind the verb. We can compare such expressions as *love overcame him*, *anger vanquished him*, Italian *l'odio si impadronì di lui*, *l'ira lo vinse*, *il terrore lo prese*, *amor mi mosse che mi fa parlare*, Greek *τῷμος δέ Φοῦ ἔλλαβε γνῖα*, *ἔρος αὐτε με λυσιμέλης δόνει*, etc.

In this problem, as in all linguistic problems, we must not compare linguistic categories with extra-linguistic realities as we see them today (as does, e.g., Bloomfield, *Language*, p. 271 ff.), but as *they were seen and conceived in the time when these categories were formed*. Language, a historical reality, can never be grasped without a deep understanding of history and of the changes of human conceptions throughout time.

Sec. 17. *The General Linguistic Trend Towards Abstraction*. The human mind tends more and more towards an abstract way of thinking; it is therefore natural that it has to find and create, by different means, a large number of abstract nouns and verbs capable of expressing new ideas and concepts. We can easily observe, therefore, that the passage from a concrete to an abstract meaning is very frequent, whereas the inverse is rare. This is one of the most evident characteristics of lexicological change. Bloomfield himself, an enemy of "mentalist" methods, gives in his book *Language* (pp. 429 f.) some good examples and seems to admit that this change is general: "The surface study of semantic change indicates that refined and abstract meanings largely grow out of more concrete meanings. [. . .] This [. . .] gives us some measure of probability by which we can judge etymologic comparisons." Centuries ago, Giambattista Vico, the Italian philosopher, had already clearly pointed out this important phenomenon. It is hard, he tells us, to enter the imagination of primitive men "le menti dei quali di nulla erano astratte, di nulla assottigliate, di nulla spiritualizzate, anzi tutte sprofondate nei sensi, tutte rintuzzate dalle passioni, tutte seppellite nei corpi [. . .]. La sapienza poetica, che fu la prima sapienza della gentilità, dovette incominciare da una metafisica non ragionata ed astratta qual è questa degli addottrinati, ma sentita ed immaginata quale dovette essere di tai primi uomini, siccome quelli che erano di niuno raziocinio e tutti robusti sensi, e vigorosissime fantasie [. . .]."

Quanto prima avevano sentito d'intorno alla sapienza volgare i poeti, tanto intesero poi d'intorno alla sapienza riposta i filosofi; talchè si possono quelli dire essere stati il senso e questi l'intelletto del gener umano."

I will add here at random the following material. The English word *idea*, perhaps the most abstract of all words, is the Greek *idéa*, which comes from the root **wid*—'to see' (older meaning in Greek *εἶδον*, 'I saw,' Latin *uideō*, Russian *vidjet*, etc.). In English *wise*, *wisdom*, we find another abstract offspring of the same root. English *sage*, French *sage*, *sagesse* come doubtless from the Latin *sapidus* (*sapiō*, *sapor*) 'having the taste of something.' Again a passage from a physiological sensation to an intellectual notion. The Latin *cogitāre* 'to think,' 'to cogitate' is a compound of *co-* and *agitāre* 'to agitate' (meaning 'to agitate something within one's mind, with oneself'). Italian *pensare*, French *penser* are nothing but half-learned parallel forms of *pesare*, *peser* 'to weigh' (Latin *pēnsāre*, from *pendere*, cf. English 'to ponder,' 'to weigh'). The *concept* is 'that which is grasped together' (cf. English *to grasp*, *to understand*, from *cum* and *capio*). *Subject*, *object* come from the verb *iacio* 'to throw' and the prepositions *sub* and *ob*. *To consider* comes from *cōnsiderāre* 'to gaze at the stars,' and *dēsiderāre* has a similar origin ('to ask something from the stars'). *Animus*, *anima* come from a root meaning 'to blow,' 'to breathe,' cf. Greek *ἀνεμος* 'wind,' etc., and so does *spirit* (*spīritus*, *spīrāre*), Hebrew *ruah*, Sanskrit *ātman-* (cf. German *Atem*), Russian *duša*, *duch*, *dyšat*, Greek *ψυχή* (*ψύχω*), *πνεῦμα* (*πνέω*). *Matter* (as opposed to *spirit*), French *matière* goes back to a Latin word meaning 'construction wood' (*māteriēs*), and so does Greek *ὕλη*, *θυμός*, 'vital force,' 'courage,' has preserved its old meaning in Latin *fūmus*, Russian *dym* 'smoke,' etc. The verbs meaning 'to be' (*be*, *was*, *is*) or 'to become' (German *werden*, Greek *γίγνομαι*, Latin *fiō*, French *devenir*, Spanish *ponerse*, *llegar a ser*, etc.) show a similar development, for 'to be' and 'to become' are very abstract conceptions.

The inverse process also exists, as I said, but is much rarer: cf., e.g., Latin *anima*, which in Romanian took the place of *cor* 'heart' (vice versa, 'heart' has taken an abstract meaning in many modern and ancient European languages: English *he has a good heart*, French *il n'a pas*

de coeur, etc. German *die Wache*, Spanish *el justicia*, *el policia*, French *le nourrisson*, English *justice of the peace*, Russian *sirotá* are now concrete.

Sec. 18. *The Linguistic Trend Towards Generalization*. Closely connected with the trend towards abstraction is the trend towards generalization (general classifications, categories, concepts). The primitive man understands only concrete objects, and therefore individual objects. His mind is incapable of grasping the common features that lie beneath apparent differences in things—which is, of course, a typically logical operation, the basis of all philosophical thinking. A *white cow* is for him entirely different from a *red cow*; he does not see or value the resemblances between the two animals. From his conception to monotheism, pantheism, and the now dominating monistic philosophies, the way is long, but the trend is continuous. Primitive tribes in all corners of the earth lack such general words as *fish*, *tree*, *bird*, *animal*, or even *cow*, *parrot* or *palm*, but they have many words for every sub-species of fish, cow, parrot, or palm (cf., e.g., Jespersen, *Language*, pp. 429 f.). And this is equally true for adjectives and verbs. "The Mohicans have words for cutting various objects, but none to convey cutting simply" (Jespersen). The same situation can be easily reconstructed or even directly observed in Indo-European languages, such as Lithuanian, which has no general word for 'gray' or 'red,' but has a word for 'gray' when *wool* is so qualified, another for *horses*, another for *cattle*, and still another for the *human hair*. The same thing occurs in the case of other colors.

Therefore, in cases like German *Lachs* 'salmon,' meaning 'fish' in Tocharian (*laks*), or of the Greek *δρῦς*, meaning both 'oak' and 'tree' (cf. also English *tree*, Russian *džerjevo* 'tree,' 'wood,' etc.), we can safely admit that the narrower meaning ('salmon' resp. 'oak') is the older (cf., e.g., Boisacq, *Dictionnaire étymologique de la langue grecque*, Heidelberg-Paris, 1923, p. 203; S. Feist, *Etymologisches Wörterbuch*, p. 481); although, of course, the inverse case (narrowing of meaning) is also known (cf., e.g., Latin *neccare* 'to kill' > French *noyer* 'to drown'; Latin *pōnere* 'to lay,' 'to put' > French *pondre* 'to lay eggs'; Latin *sēparāre* 'to separate' > French *sevrer* 'to wean'; Vulgar Latin *labōrāre* 'to work' > French *labourer* 'to till,' 'to plow.'

Sec. 19. *Anomaly in Grammar.* Anomalous, irregular forms, called very improperly suppletive, are usually old, for the very simple reason that analogy, the trend toward *equalization* of paradigms and even toward the *formation* of paradigms, works constantly toward the elimination, not the creation of irregular or suppletive forms (such as French *je suis, je fus*, Latin *ferō, tulī*). It is clear that such a paradigm as *amō, amāuī, amātus, amāre* is recent. This analogy is after all only one current in the great river of generalization of which we have spoken in the preceding section. The psychological urge is identical in both cases, only in one it acts on vocabulary, in the other on morphology (on the value of this distinction, see below). On this point, Jespersen has given the right answer (*Language*, p. 426): "In an interesting book, *Vom Suppletivwesen der indogermanischen Sprachen* (1899), H. Osthoff has collected a very great number of examples from the old Aryan [Indo-European] languages of different stems supplementing each other, and has pointed out that this phenomenon is characteristic of the most necessary ideas occurring every moment in ordinary conversation [because these words are always better preserved, for obvious reasons. G. B.]: I take at random a few of the best-known of his examples: French *aller, je vais, j'irai*, Latin *ferō, tulī*, Greek *horaō, opsomai, eidon*, Latin *bonus, melior, optimus*. Osthoff fully agrees with me that we have here a trait of primitive psychology: our remote ancestors were not able to see and to express what was common to these ideas; their minds were very unsystematic, and separated in their linguistic expressions things which from a logical point of view are closely related."

Sec. 20. *The Creation of the Article.* Another interesting case is offered by the creation of the article, which is very definitely a sign of linguistic progress. We can observe its birth and growth in many languages, but never its disappearance. It is exactly the opposite of the dual. The psychological reason is given by Sommerfelt, *La langue et la société*, pp. 196 f.: "It cannot be doubted that the development of linguistic categories, just as of other facts of material and spiritual civilization, is explained by the differentiation of society under the effect of the necessities of social work [. . .]. The Latin word *petra* means at once 'the stone,' 'stone' and 'a stone.' The article has come to

express the more concrete meaning, 'the stone in question,' while the old form, without the article, represents the general meaning. It is only when the need was felt to distinguish the general meaning from the concrete case that the article was created; the new form provided with the article corresponds better to the meaning of the Indo-European noun than the old form without the article. Perhaps the same happened in the case of the adjective and the noun."

Sec. 21. *Poetical Character of Semantic Changes.* Besides the general semantic trends we have indicated above, other changes are found in vocabulary. They have been classified in a series of works, some of which are cited in the bibliography, and we need not go into details here. We find in semantic change, besides the trend towards generalization or an extension in meaning which we have considered above, the *restriction in meaning* (much rarer than the opposite), as in French *pondre*, 'to lay (an egg),' from the Latin *pōnere* 'to lay,' or in *hound*, originally meaning 'dog'; the *degeneration*, as in *knave*, formerly meaning 'servant' (cf. German *Knabe*); the *elevation*, as in *knight*, originally meaning 'servant' (cf. German *Knecht*), etc. The chief characteristic of semantic change, however, is that (if we disregard those of a purely social nature, such as *marshal* from *maréchal* [-*ferrant*], which strictly speaking do not belong in an Encyclopedia of Psychology) it can be, and usually is, defined in terms of rhetorical, that is, poetical figures, such as metaphor, metonymy, synecdoche, hyperbole, litotes, antonomasia, pleonasm, ellipse, prosopopoeia, catachresis, irony, euphemism, and so on. Croce's philosophical identification of language with poetry is entirely confirmed from the technically linguistic side. The German who first said *Augenstern* for 'pupil,' the Norseman who first said *vindauga* (*window*) 'eye of the wall,' the first Greek who said ψυχῇ 'soul' for 'butterfly,' the first Italian who used *pacare* 'to pacify,' with a twinkle in his eye, in the sense of 'to pay' (*pagare*) were poets, in their own humble fashion, and the eternal sparkle of Dante and Shakespeare was kindled for a moment in their hearts.

Sec. 22. *The Names of the Pupil.* If we open again the *Linguistic Atlas of Italy*, at map No. 101 (*occhio*), we will notice that representatives of the Latin word *oculus* occupy without

a single exception (excluding the Albanian and Greek localities) the whole map. The same can be said more or less of most of the other parts of the body, such as 'foot' (*pie*de), 'forehead' (*fronte*), 'knee' (*ginocchio*), 'bones' (*ossa*), 'skin' (*pelle*), 'blood' (*sangue*), 'vein' (*vena*), 'ear' (*orecchia*), etc. But if we look at the side of the same map *occhio*, where a few names for 'the pupil' (of the eye) are reproduced, we will be struck not only by the great variety, but by the peculiar character of these names: human fantasy has taken here its most audacious flights. The Latin name *pūpilla* (literary Italian *pupilla*) is rare; we find in its place *la lūneta* 'the little moon,' *il lūmin di ōē* 'the little lamp of the eyes,' *la lūz di ōē* 'the light of the eyes,' *la pūtina* 'the little one,' *l'animeta dey ōū* 'the little soul of the eyes,' *la madunena* 'the little Madonna,' *la puparella dal ōēg* 'the little doll of the eye,' *la pallotta dal ūēē* 'the little ball of the eye,' *la vetrella* 'the little glass,' *la palum-mell*^a 'the little wood-pigeon,' *a ninne del ūōēē* 'the girl of the eye,' *la tsitts*^a 'the teat,' *l'iom*^a *dal ūōēē*^a 'the man of the eyes,' *a siñurell*^a 'the little lady,' *a prunedda* 'the little plum' (cf. French *la prunelle*), *l'ancalēda* 'the little (female) angel,' *la luccglell*^a 'the little firefly,' and other more or less obscure words. More would surely be found if the map were complete, and can be found in dialectal dictionaries or special works (e.g., French *voyant*, Sardinian *candela di ogu*, *laddara* 'gall-nut,' etc), like that of Zauner in *Romanische Forschungen*, Vol. 14, 1903, pp. 336 ff., or of Wagner, *Studien über den sardischen Wortschatz*, p. 71. We could be tempted to attribute this outburst of imagination to the artistic nature of the Italians, which, of course, in general cannot be denied. But in this case, this is at least doubtful, for we find *Augenstern* 'star of the eye' in German, *anha* 'lamb' in Provençal, *pūpilla* (from *pūpa* 'doll,' 'girl') in Latin, *κόρη* in Greek, *prunelle* in French, *niña* in Spanish, etc. Obviously the little dark, perpetually moving spot in the eye where a little image appears and which seems to concentrate in itself the very mind and soul of man, cannot be put on the same level with words like 'foot' or 'ear' or 'knee,' or even 'eye,' which are at least to our modern minds simply prosaic indications of objects. There is something else here, and something much more important than the mere need of communicating an idea to another man.

Sec. 23. No Semantic "Laws" Exist. No semantic "laws" exist, or can exist, of course, just as no "phonetic laws," or "morphologic laws," or "linguistic laws" in general can either. Language is poetry—that is, creation and freedom—and no "laws" can be imposed on man as he creates language any more than when he creates a work of art. This does not mean that language is chaos, for a work of art is not chaos, and moreover it would be just as incomprehensible as a chaotic work of art (which is a *contradictio in adiecto*). Dante was entirely free when he wrote the *Divina Commedia*, free to write or not to write, to choose this or that subject, to treat it in one way or another, viz., to use hendecasyllables or other verses, to divide it into fifty or a hundred or two hundred songs, to introduce this or that person with these or those words or expressions or thoughts, and so on. But all these possible variations do not mean at all that the *Divina Commedia* is arbitrary, chaotic or absurd; it has its inner logic, which makes out of it a well-rounded whole, which reflects the inner harmony of Dante's sublime personality. This inner logic is of course a human, interior, and artistic logic, not the abstract, mathematic Cartesian or Aristotelian logic. So it is with language, which has its own interior logic and harmony, its system, not imposed from without, but given from within, by the logic of its own existence.

Semantic changes are, therefore, logically unexpected and strange, although psychologically quite understandable. There is no necessity in them. When the European peoples entered into a commercial culture, they had to create (or recreate) verbs meaning 'to pay.' Such a concept can recall to us several ideas, such as 'to disburse money,' 'to become poorer,' or metaphorically 'to cut one's leg,' and the like. As a matter of fact, none of these was ever used, but other expressions were. German said *bezahlen* 'to count (the money)'; Latin said *solvere* 'to dissolve,' 'to destroy' (an 'obligation'); Vulgar Latin changed the verb, and chose *pācāre* 'to pacify' (scil. the man who asks for his money). What impressed the Vulgar Latin speaker was not the juridical obligation (which was essential for the juridically minded ancient Roman who used *solvere*) but the idea of getting rid of a creditor who bored him with his angry insistence. Each language was free to choose its own way of expressing the same idea. None

was logically necessary, as is proved by the fact that the origin of each of the three words is entirely different.

However, it is a fact that certain mental associations, although not quite evident or immediate to us when we think logically, are so frequent in many different languages as to suggest that they must come immediately to the mind of the speaker when he is looking for a word. We have seen above that in many different languages the 'pupil of the eye' is a girl (many more examples could be added), an image which is by no means necessarily suggested by looking at the pupil (nor is the pupil always called like this!). Likewise, when the European languages had to find a new word for the new idea of 'work,' almost all of them went back to the idea of 'labor,' 'hardship,' 'torment,' 'torment' (German *Arbeit*, French *travail*, Italian *lavoro*, English *work*, *toil*, *labor*, etc.). This was obviously how work impressed them psychologically, although other solutions (such as 'production,' 'way of earning money,' 'fatigue,' 'exertion,' 'exhaustion,' 'duty' or what not) seem to be just as good to us logically. The idea of 'wretched,' 'miserable' frequently evolves from words meaning 'foreigner,' 'prisoner' (German *Elend*, Italian *cattivo*); words meaning 'wicked,' 'bad' from words meaning 'sad,' 'wretched,' 'unfortunate,' 'miserable' (Italian *cattivo*, *tristo*, *disgraziato*, *sciagurato*, English *wretch*, French *mauvais*, *un misérable*, *méchant*). So we have seen above that words for 'soul,' 'spirit' almost regularly come from words meaning 'to breathe.'

Language, I would like to stress, is spoken by men, and men do not see reality as it is, objectively and scientifically, but as it impresses them subjectively; man as a speaker, a creator of language, is not a mathematician, a logician or a scholar: he is rather an artist, an eternal child, a creature of emotions, fears, strivings, desires, and dreams. Instead of imposing our theories upon language, we should learn from it. It has much to tell us. Voltaire saw this fact, and expressed it with his usual clarity, writing: "aucune [langue] n'a pu être formée par une assemblée de logiciens." (*Dict. philosophique, article Langue*).

Sec. 24. *National Psychology in Lexicon*. But besides these universal tendencies based on the common elements of human nature, there must be some trends and facts characteristic of a

single nation, which reveal to us the peculiar mentality, for example, of the Germans, the Russians, the Italians. These are not easy to find, even if we take into account the reservations made in Section 10. For some reason, it is much easier to discover the universal psychological trends of language or the individual psychological characteristics of the language of an individual than national characteristics.

We will, of course, omit those linguistic facts which reflect social or material conditions, such as *marshal* from French *maréchal*, originally 'shoeing-smith' (cf. *maréchal-ferrant*). The *marshal* was once the 'shoeing-smith of the king,' a post of great honor in France. It became later a title of command in the French Army. This change is entirely dependent on social and political conditions in France, a country once having a strong and respected monarchy. It could not have happened in Italy, the land of the free Republics and Comuni. But this semantic change betrays little of the psychology of the French nation, except that its social structure was once strongly monarchistic. These and other facts belong in an Encyclopedia of History or Social Sciences, rather than in an Encyclopedia of Psychology.

But in some cases a nation's way of life, its interests and occupations influence so much its way of thinking that they are strongly reflected in language, even outside of the technical sphere to which they originally belonged. It could be shown how art and music have influenced Italian, how many expressions and semantic changes in German have originated in the army, how hunting, the chief occupation of Medieval French noblemen, has introduced into the common language a series of words. The American language is full of expressions drawn from the world of business, industry, and sports, things which have a great importance in American civilization (cf. e.g., *handicap*, *knock out*). We will consider here the case of archaic Latin. The ancient Latins, Marouzeau says, were chiefly a people of peasants—a fact proved by abundant historical and literary sources. The strong, patient, courageous, and parsimonious Roman peasant was the backbone of the Republic. His virtues were always considered the ideal of Roman character. This, Marouzeau says, is reflected very much in the language. 'To consider' is in Latin *putāre* 'to prune'; 'the good man,' *ægregius*, is 'the one (sheep) chosen from

the flock'; *aggregāre* was 'to add to the flock' (cf. also *congregāre*, *sēgregāre*); 'rich' is *locuplēs*, 'the (man) full of land' (from *locus* and the root **plē-* of *plēre*); 'poor,' *pauper*, was originally applied to a field which 'produces little' (from *pau-*, cf. *pau-cus*, *pau-lus*, Engl. *few*, and *pariō*); *dēlīrāre* 'to be delirious' meant originally 'to go out of the furrow' (cf. *lira* 'furrow'); *praeuāricārī* 'to prevaricate' was applied in the beginning to the plowman who plowed crookedly (cf. *uārus* 'baker-legged'); *stimulāre* 'to stimulate' was 'to goad (oxen)' (cf. *stimulus*); 'to hasten (an enterprise)' was 'to mature it,' *mātūrāre*; *laetus* 'joyful' was applied originally to a field well-manured (cf. *laetāmen*, 'dung,' Italian *letame* 'dung'); *fēcundus*, *fēlix* were applied to productive trees (*fēlix arbor*); 'a country' is in Latin *ager* 'the field,' (*ager Nōricus*, *ager Hirpinus*, etc.); even the usual verb meaning 'to do,' 'to be active,' which was very close to becoming a vicarious verb, as *to do* in English (*how do you do?* = *quid agis?*), once had the meaning 'to push (the flock).' It is a known fact, already remarked by the ancients, that the best Roman families had names taken from the land, as *Porcī*, *Asinī*, *Fabī*, *Lentulī*, *Cicerōnes*, *Caprārī*, *Onidī*, etc. To be called *Onicula* would be an insult to modern man; it was a compliment for a Roman.

On Italian, we may read e.g., the opinion of such a prudent scholar as Bourciez, *Éléments de linguistique romane*,³ Paris, 1930, p. 505: "Above all, Italians are a race of artists: we can feel that in an adjective like *leggiadro*, where from the idea of lightness, of slimness, they rapidly pass to the meaning of 'pretty,' 'agreeable'; likewise in *vago* 'wandering,' which arrives to the meaning of 'charming' through intermediary of the language of painters where it indicates the hazy and vaporous of a picture. See finally how out of *disinvolto* (= **dis-inuolūtus*), that is, 'disencumbered of that which enveloped it,' has successfully emerged an idea of ease and freedom in manners."

Similar remarks, making an interesting coincidence, may be found in J. Schrijnen, *Einführung in das Studium der indogermanischen Sprachwissenschaft* (trans. Fischer), Heidelberg 1921, pp. 70-1: "But language is also an artistic construction, the expression of the varied life of concepts and feelings. It is a spiritual product of art of the various social conditions. One speaks

not only because of the need for social communication, but also out of pleasure and leisure. This is clearly seen in children and common people who sometimes cannot help but give free rein to their necessity for speaking. Speech in the widest sense of the word is an utterance of beauty, and as such its chief requisite is strength and power to express and to distinguish nuances. The capacity of Italian for example to make from *casa* words like *casino*, *casina*, *caserino*, *casetta*, *casella*, *caserella*, *casuccio* [read *casuccia*] on the one hand, *casaccia*, *casone*, *casatto* [read *casotto*], *caserna*, *casamento* on the other hand in order to express the concepts or rather the shades of feeling 'little-lovely, big-crude'—this capacity proves that the people form and transform, understand and feel their language with an artistic sense. It evidences the strongly pronounced feeling of the language on the part of the Italians and the high expressive value of the Italian suffixes." Alfred de Musset, a French writer of delicate feeling, although not a linguist, understood another Italian quality when he wrote in *Le fils du Titien*: "*Simpatica*, Italian word of which our language [= French] does not have the equivalent, perhaps because our character does not have the equivalent of that which it expresses" (cf. H. Schuchardt, *Literaturbl. für germ. und romanische Philol.*, 39, 1918, p. 285). It is therefore not at all a chance that W. Somerset Maugham, in his novel *Up at the Villa* (Doubleday, Doran and Company, New York, 1921, p. 152), in reproducing in English the speech of some Italians, leaves the word *simpatico* untranslated: "They'd let him owe money for three weeks because he was so *simpatico* [. . .]."

And who does not feel the heritage of classical moderation and wisdom in Italian *accorto*, *prepotente*, *senno* (although this is a word of Germanic origin), the French elegance and *finesse* (!) in French *joli*, *chic*, *charmant*, *délicieux*, *adorable*, *nuance*, the English morality in *fair-play*, *gentleman*, (good) *sport*, *shocking*, the German romantic feeling in words like *Sehnsucht*, *schmachten*, *hinsiechen*, *Wahnsinn*, *bange*, *Stimmung*, *Weltschmerz*, *Gemüt*?

Words typical of a country and of a culture are, of course, difficult to translate into another language; they are usually simply introduced in foreign tongues without any change. So the French word *nuance*, which expresses most of

the secret charm of French art and literature, and of French culture in general, has penetrated *sic et simpliciter* into the great neighboring languages, English, Italian and German, because no native word was available to express exactly that *nuance* of meaning. One of the most characteristic and illustrious French poets, Verlaine, wrote in what is rightly considered the *manifesto* of his school, the poem *Art poétique*:

Car nous voulons la Nuance encor,
Pas la couleur, rien que la nuance!
Où la nuance seule fiance
Le rêve au rêve et la flûte au cor!

The English word *gentleman*, concentrating all the qualities of correct behavior, good manners, honesty, loyalty, endurance, seriousness of purpose, that have made the English nation great, is frequently used in its English form in continental Europe to designate, e.g., a native *Frenchman*, *Italian* or *German* who possesses, or is supposed to possess, the qualities that the word indicates.

Sec. 25. *National Psychology in Grammar*. This demonstration is not very difficult, in some cases, for the vocabulary; it is much more so for grammar. Several attempts have been made, as stated above, especially by German scholars, but not all of them have met with undivided approval. I will mention here the recent work of a very brilliant American young lady who studied under Spitzer, Anna G. Hatcher, of Johns Hopkins University. In a careful comparison between the reflexive use of verbs in Latin, Old French, and Modern French (*Reflexive Verbs, Latin, Old French, Modern French*, Baltimore, London and Paris, 1942). Miss Hatcher reaches important conclusions. She writes e.g. (p. 149): "As for the type *soi apercevoir*, which represented the combination of a verb of apperception plus *soi* = 'one's situation' (*son estre*), most of the verbs formed in Old French have remained [in Modern French]: *s'apercevoir de*, *se connaître à*, *s'aviser de*, *s'oublier*, *se reconnaître à*. From the first three, the idea of 'awareness of one's situation' has faded. But all of them alike are merely relics: monuments of another age in which there prevailed a different attitude toward the Self—according to which the Self that could be perceived by the subject was only Self-in-a-certain-situation. But in the modern language *son*

être has a reference more 'essential' than had Old French *son estre*: it represents the Self, the Ego, the *Moi*. Today it is considered possible to contemplate the Self as an isolated entity (cf. *s'analyser*), and an *apercevoir soi-même* if coined today would be quite a different verb." And elsewhere (p. 155): "In Old French [. . .] such verbs [of self-restraint, as *se modérer*, *se retenir*, *se reprimer*, *se vaincre*, etc.] were rare, and even so, were regularly used negatively—with the exception of *se contenir*, frequent in the more courtly literature. The exuberant heroes of the Chansons [de geste] were portrayed more often as expressing than as repressing themselves. But with the verbs above we are back once more in the Ciceronian [Stoic] atmosphere of *sē cohibere*, *reprimere*, *coercere*, etc."

Such studies are of the greatest importance, and, even if we are not convinced of their results, we should by all means encourage them, because they tackle one of the most difficult and important problems of linguistics and psychology. But for the moment, I remain in doubt whether many of the facts pointed out so cleverly by Vossler, Spitzer and their followers might not be explained in terms of general human evolution, according to Sec. 14, with the modification perhaps offered by Vico's theory of the *corsi e ricorsi* (recurrent phases of history). The Middle Ages, the epoch of the Chansons de Geste mentioned by Miss Hatcher, could perhaps be, from certain points of view at least, a relapse into more primitive, mystic and barbaric ways of thinking, whereas the French world after the Renaissance, under the influence of Italy, takes up again the philosophical, rational and scientific trend of Classical Antiquity. This could explain the affinities in linguistic expression between the Modern and the Pagan world as opposed to the Middle Ages. But the French development would then be, more than something specifically French in the national sense, an episode in the great march of all humanity from a mystic to a rationalistic and objective conception of the world. The same can be said of the excellent studies of the Swiss-French scholar Charles Bally.

Sec. 26. *Language and Folklore*. Folklore and superstitions of every kind play an important part in language, more perhaps than scholars usually believe. One of the animals around which popular fantasy has woven many tales is

the *weasel*. In Aesop's fable "The Weasel and Aphrodite" (88 edition Halm, p. 43; 76 edition Chambry; 50 edition A. Hausrauth, *Corpus fabularum aesiopicarum* I, Leipzig, 1940, pp. 69 f.), "a weasel falls in love with a handsome young man, and asks Aphrodite to change her into a woman. The goddess takes pity and transforms her into a beautiful girl; and so the young man, seeing her and falling in love with her, brings her to his house. But while they are sitting in the matrimonial room, Aphrodite, wishing to know whether the weasel was transformed in nature as well as in body, sends a mouse into the middle of the room, and she [the weasel], forgetting all the present things, rises up from the couch and hunts the mouse, to eat it. And the irate goddess restores her to her old nature."

This and many other legends and superstitions are reflected in the names of the animal. In England she is *the fairy*, in Bavaria *jüngerchen* 'little virgin,' or *Schön-tierlein*, *Schöndinglein*, in Westphalia *Fröie*, in the Sette Comuni *Vraule* (= *Fräulein*), in German Moravia *Geatterlein* 'little god-mother,' in Old Czech *panna* 'young lady,' in Georgia *dedop'ala* 'queen,' in Modern Greek *νυμφεῖα* 'the bride,' in Serbian *nerjestica* 'bride,' in France *la belette* 'little fair one' (from *belle*) or *daunabera* 'the beautiful lady' (*domina bella*) or *poulido* 'the pretty one' (from the Latin *pōlita*), in Spain *mona* 'the pretty one,' *comadreja* 'god-mother,' *norinha* 'little daughter-in-law,' *donocina*, *paniquesa* (from *pan y queso* 'bread and cheese'), *garridiña* (perhaps 'thrifty one'), in continental Italy *bejannuccia* 'the Epiphany' (usually represented as an ugly old woman, bringing gifts to children), *massairela* 'the little housewife,' *panakāšu* (from *pane e cacio*), *donnola* 'the little woman,' *mannakēdda* 'little nun,' *tstola* 'little one,' *kuca* 'little dog-bitch,' in Sardinia *yana'e muru* 'fairy of the wall' (also by popular etymology *yanna* or *enna e muru* 'door of the wall'), *comar' Anna* (cf. St. Anne), *anna e muru*, *dana e mele* 'fairy of the honey,' *nonna e mele* 'the godmother of the honey,' *can e meli* 'dog of the honey,' *melimbukka* 'honey in the mouth,' *bukkameli* 'honey-mouth' (and further by popular etymology *bucca e mela* 'mouth of the apple,' *vae de mela* 'boat of the apple'), and many others. English *weasel* is perhaps 'the gay one' (connected with Russian *vjesjē* 'gay'); cf. the Latin name *hilaria* (Keller, *Die antike Tierwelt*, p. 164).

Many other animals and plants offer similar phenomena, such as the *owl*, the *fox*, the *dragon-fly*, the *firefly*, the *spider*, the *turtle*, the *butterfly*, the *bat*, the *dove*, the *squirrel* (from Greek *οἰουρος* 'he who shades himself with his tail') and others, and their names are sometimes difficult to understand: man's imagination, once stirred, works fast and with no concern for mere logic or investigating scholars. But it is clear that there is no hope of understanding any of these facts without a mind open to the real workings of the human psyche and a thorough knowledge of popular beliefs and superstitions.

Sec. 27. *Linguistic Taboo*. The problem of linguistic taboo is so closely connected with that of the preceding paragraph that it is frequently difficult to keep them apart. We can define *taboo*, in its original meaning, as the avoidance of a word (and its replacement by another word) caused by fear of a supernatural power. The most frequent taboo is, of course, that of the supernatural being itself (god, demon, etc.). Sometimes the god (or goddess) is called 'the good one,' even if he is dangerous and cruel, and particularly if he is dangerous and cruel. The Greeks said *Εὐμενίδες* 'the benevolent ones,' instead of *Ἐρινύες* (these goddesses are surely *not* *Εὐμενίδες*!); the Romans called the infernal gods, who take our lives from us, *Di mănēs* 'the good ones'!

Names of wild animals are frequently taboo, probably because they were free beings, independent of man, demon-like and sometimes incarnations of men. "Bear" was doubtless taboo among some Indo-European peoples: cf. Russian *mjeduždjē* 'the honey-eater,' English *bear* 'the brown one,' etc. English *hare*, German *der Hase* was once 'the gray one,' Greek *λαγώς* 'the slack-eat.' Some parts of the body are also conceived as living beings, as dangerous forces (see above). Most Indo-European words for the parts of the body are stable, e.g., *the heart*, *the knee*, *the tooth*, *the ear*, *the brow*, *the eye*, *the chin*, *the foot*, etc., all of which are in English old Indo-European words, easy to find in Latin, Greek, Slav, etc. But the names of *the hand*, *the finger*, and *the hair* vary constantly, so that it is absolutely impossible to reconstruct any Indo-European form for them. However, since the Indo-Europeans possessed these parts of the body, and since they certainly mentioned them, and since we see no other reason why these

words should have been eliminated, we must conclude that the old words were tabooed. As a matter of fact, *the hair, the hand, and the finger* are believed to have terrible magic powers (cf. the hair of Sampson, 'the hand of God,' etc.).

Linguistic taboo is extremely strong among primitive tribes, as is known from innumerable reports of missionaries and scholars. But it is also known, e.g., in classical and Jewish antiquity. The *flāmen dīālis* at Rome could not touch raw meat, ivy, a she-goat, beans, corpses, nor pronounce their names. The Jews were (and are still) not allowed to pronounce the name of Jehovah. Linguistic (and also non-linguistic) taboo still exists in our modern society, although to a much more limited extent. We say *the Lord* or *the Almighty* for *God*, *our Lady* or *the Virgin* for *Mary*, etc. And even such deformations as American *gosh* for *God*, *heck* for *hell*, French *sapristi*, *parbleu*, *pardi* for *sang Christi*, *par Dieu*, Italian *cribbio* for *Cristo* and *madosca* for *Madonna* can well be classified as taboo. But the taboo of *the hand*, of *the finger*, and of *the hair* seems to have disappeared: Cf. English *hand*, *finger*, *hair*; German *Hand*, *Finger*, *Haar*; French *main*, *doigt*, *cheveu*; Italian *mano*, *dito*, *capello*; Spanish *mano*, *dedo*, *cabello*, etc.

Sec. 28. *An Uncertain Case: Old Irish súil* 'Eye.' Sometimes we can remain in doubt between several explanations. The Indo-European name for 'the eye' (Latin *oculus*, English *eye*, etc.) has been replaced in Old Irish (*súil*) by the name of the 'sun' (Latin *sōl*, etc.): the 'sun' is therefore thought of as 'the eye' of the sky, or of the whole universe (the eye had a radiating power among primitive tribes, and even, e.g., in Dante's times); cf., e.g., Homer, *The Iliad*, 3, 277, ἡέλιός θ' ὅς πᾶν' ἐφορᾷς καὶ πᾶν' ἐπαυροῖς, and see Macdonell, *Vedic Mythology*, p. 307. Is this a taboo? Is it imagination, poetry, superstition, mythology, religion? Shall we think of Italian poetry, in which the eyes of a fair lady are almost regularly compared to suns, of the beautiful verses of Ariosto *Sotto due negri e sottilissimi archi Son due negri occhi, anzi due chiari soli?* After all, is this distinction a very important one? Do not poetry, feeling, imagination, religion spring from the same source in man's soul? The only thing that matters is that all these motives are entirely distinct from logics, philosophy, science,

rational thinking, mathematics; that no amount of logics, of utilitarianism or mechanism can ever explain why the Irish called the "eye" "sun," whereas the verses of Ariosto easily can; and that this and most changes of meaning remain entirely incomprehensible as long as language is considered uniquely as a "means of communication," a sort of mathematics for the transmission of bank accounts.

Sec. 29. *Other Linguistic Interdictions.* Some scholars extend the name of taboo to every sort of linguistic interdiction, the fundamental motive being always *fear*. Names of objects or places or persons bringing bad luck are avoided or transformed. The Romans changed the name of the town of *Maleventum* into *Beneventum*, the Greeks, the πόλις "Ἀξείνος (an Iranian word meaning 'dark,' cf. Avestan *axs'aēna-*) into Εὐξείνος 'hospitable, because "Ἀξείνος sounded to them like 'inhospitable.' In our modern society, the interdiction of the *left hand* still seems to be very strong; while the names of the *right hand* are more or less the same in the different European languages (the word *right* being very frequently the same as *right*, the opposite of *wrong*, as it is in fact in English), the names of the *left* change frequently: English *left*, German *linke*, Gothic *hleiduma*, Norwegian *venstre*, French *gauche* (of Germanic origin), also *seneko* 'the old one,' Catalan *esquerra*, Spanish *izquierda* (of Basque origin), Italian *manca*, *mancina*, *stanca*, Romanian *sting*, etc.; but cf. English *the right hand*, German *die rechte Hand*, French *la droite*, Spanish *la derecha*, Italian *la (mano) diritta*. The names for the *left* are frequently words meaning 'old,' 'weak,' 'bad,' 'tired,' 'crooked,' 'mutilated,' 'withered,' 'faint,' 'flaccid,' etc., or are foreign words. The left hand brings bad luck, cf. English *sinister* from the Latin *sinister*, Italian *sin sinistro* 'an accident,' etc., or has in general a bad connotation: French *gauche* 'awkward,' 'clumsy,' *mariage de la main gauche*. "In Heaven, the good Christians will be seated to the *right* of Christ, the bad ones to the *left*" (cf. Matthew, 25, 33, and the *Dies irae*; cf. F. Ermini, *Il Dies irae*, Geneva, 1928, p. 144: *et ab haedis me sequestra statuens a parte dextra*). Greek ἀριστερός (from ἀριστος), εὐώνυμος, Norwegian *venstre*, Old Irish *túath*, etc., are typical taboo names, that is, euphemisms, like Εὐμενέδης (see above Sec. 27).

Euphemisms for 'to die' are frequent and

well known (*to pass, to go west, to de cease, to leave this world, to kick the bucket*, etc., Italian *tirare la calzezza*, Spanish *espichar, estirar la pata*; cf. also English *to die*, German *sterben*, originally 'to starve'; cf. English *starve*). *To kill* is a verb which changes frequently: cf. English *to kill*, German *töten, umbringen*, Gothic *us-giman*, Greek *κτείνω*, Latin *occidō, interficiō* (also a taboo word: 'to make away with'), Russian *ubit'*, etc. In the Romance languages we have French *tuer* (from *tūdre* 'to extinguish [a light]'), Spanish *matar*, Romanian *omorā*, Italian *uccidere, ammazzare, accoppiare, scannare, fare la pelle*. The English *to slay* was once 'to beat' (German *schlagen!*), cf. Russian *ubit'*, Latin *occidere*; today such metaphors as *put to sleep, take care of* (Damon Runyon) are frequently used in the United States. On the other hand, such ideas as 'to be born' or 'to live,' where always the same verb is found in the two groups of languages: English *he is born*, (Lucas 2, 11), etc., etc., French *naître, vivre, to live*, German *leben, er ist geboren*, Dutch *leven, hij is geboren*, Gothic *liban, gabaurans ist* Italian *nāscere, vivere*, Spanish *nacer, vivir*, etc., all directly from the Latin *nāscī, vīvere*. Another concept subject to frequent interdictions is *sick, ill*.

A word having a bad connotation, and therefore frequently exposed to changes and substitutions, is 'bad' itself (*wicked, evil*, etc.). If we compare it with its opposite 'good,' we can clearly see the contrast: Dutch *goed*, Swedish and Danish *god*, English *good*, German *gut*, Gothic *goþs*, but English *bad, wicked, evil*, German *schlecht, böse*, Dutch *kvaad*; and so French *bon*, Spanish *bueno*, Romanian *bun*, Italian *buono*, all from the Latin *bonus*, but French *méchant, mauvais*, Spanish *malo*, Engadinian *navš* (<nausea), Romanian *reii* (Latin *reus*), Italian *cattivo, malvagio, tristo*. On the Linguistic Atlas of Italy we find also *malu* (Sardinia, Sicily, Calabria), *llayru, ttintu, skiffyuz^a, nun servi* (verbal), *e mmalament^e, malin, lā^a, foténto* (= 'stinking'), *tsillus^a, tristo, péssama, nom malo* (= 'non vale') *brut^a, gram, marriu, fayi, vilén, mōve*; but with two single exceptions we always find the type *buono* (on four maps) for 'good.' The words meaning 'bad' are usually words which formerly had no bad connotation (*cattivo, tristo*, etc.).

A very frequent interdiction is that of the name of the 'mother-in-law' (and, less fre-

quently, of the other 'in-laws'): Spanish *madre política*; *padre político*, Engadinian *si^r, si^r*, Italian (dialect) *madona, ma grāda, nonno, mamma, mama d la moy, matreña, mama d leño* ('mother of wood'), *cara, dudd, la orra da mi jana; mase, mun slar, babbo, nonno, bāt^a da leño, patreño, vec*, French *belle-mère, beau-père, beau-fils, belle-fille* (also *bru*, of German origin), typical taboo-forms (the first two also replace *mānātre, parātré*, which are used today only in a clearly pejorative sense). The interdiction of all words connected with sex and some other physiological functions is, of course, well known in our modern society, where it seems to be much stronger than it was in the past (it is also much stronger in certain countries than in others).

Sec. 30. *Linguistic Geography; the Connection Between Linguistic Phenomena and Other Activities Proper of Man*. Linguistic geography, a method created by Gilliéron with his *Atlas linguistique de la France* and developed theoretically by the Italian neolinguistic school, has put the entire science of linguistics on a new and extremely fruitful road. While linguistics of the nineteenth century studied language on an exclusively historical (*diachronic*) basis, on the axis of *time*, linguistic geography studies language *synchronically*, in extension, on the axis of *space*. It enables us to see language in its totality, in all its infinite variety. The older school studied each phenomenon separately, comparing *one* French word or sound with a Latin word or sound—and supposing the existence of such blocks like French, Italian, which, when seen on a linguistic map, dissolve into an endless chain of ever-changing dialects and patois. Of the many and important discoveries of linguistic geography, we will stress here the one which is of the greatest interest for psychologists: the birth and diffusion of linguistic innovations, which enable us to penetrate into the most secret mechanism of linguistic creation itself, and to discover its deep connection with all other human activities, such as religion, art, politics, philosophy, literature, superstition, law, customs, clothing, dances, folklore. If we look at any map of the linguistic atlas of France, Italy, Romania, U. S. A., or any other atlas, we find one or two or more names (for 'horse,' 'head,' 'bee,' etc.) or forms which are *perfectly equivalent in meaning*, since exactly the same question was asked at all points

of those atlases (several hundred for each of them). Of these words or forms, one will be older, one younger (in the case of two words; in the case of three or more, there will be a hierarchy of antiquity: A, B, C, and so on: A will be older than B, B older than C, etc.). Limiting ourselves to the case of two words, if we call A the older word, B will be the *innovation*, the new word or form, equivalent in meaning and function to A, which it is gradually replacing, and will replace in the course of time, unless unexpected events happen. It will be easy to observe that, in the great majority of cases, innovations (new words or forms) are born in the great centers of culture of every nation (Paris for France, Florence [now Rome] for Italy) and spread more or less rapidly to the rest of the country, or rather "linguistic area," following with amazing regularity the great roads of communications through great valleys and plains, avoiding for a long time (sometimes hundreds or even thousands of years) the less accessible regions, such as mountains and islands, particularly the latter. We have, therefore, before our own eyes, the history of language itself. Old forms or words are not only preserved in old texts or documents: they are also—and often much better—preserved in the mountains of Rhaetia or in Sardinia (as far as the Romance languages are concerned). If we now turn to other human activities such as art, literature, law, dance, we will notice exactly the same phenomenon—the innovations irradiate from the same great centers of culture (Florence or Paris, in our example), expand on the same lines, and reach at a late date, or do not reach at all, those same isolated areas where the most archaic forms of language are found. Sardinia, where a type of Latin is preserved that is in many respects more than two thousand years old, also presents in law (*vendetta*), customs, folklore, and industrial technique an extremely old way of life. The opposite is true for Paris and Florence (now Rome), great centers of unceasing fermentation, creation and renewal of ideas and habits. The parallelism is absolutely perfect, and reveals language to be nothing else but one of the expressions of the human spirit.

Sec. 31. *Linguistic Prestige*. Another very important conclusion to be drawn from the study of linguistic geography, and one which the Italian neolinguists have particularly stressed,

is the enormous importance of linguistic prestige. It is because of its superior prestige that the French peasant, or even the citizens of Lyons and Marseille, imitates the Parisian word or expression, that of the local baron, lawyer, priest or apothecarian of his village. This linguistic prestige is, above all, a cultural, spiritual, literary, religious, artistic prestige, not a political, military, or economic one. It is the more or less conscious recognition that a certain type of culture, the vehicle of which is a certain language, is superior to one's own. History furnishes us with some striking examples of this fact. It was just after the dreadful catastrophe of the Peloponnesian war, when Athens had lost forever its military and political power, together with its economic prosperity, that the Athenian language spread victoriously over all the Grecian countries, completely uprooting the glorious old dialects, with the insignificant exception of Tsakonian. Later, in the Roman Empire, Latin easily conquered Sicily, Sardinia, Gaul, Spain, Rhaetia, Dalmatia, and Dacia, but it stopped dead at the gates of the Greek world. It never overcame any Greek linguistic area, although the defeated Greeks of the province *Achaia* were subjected to Roman rule just as the other peoples of the Empire. On the contrary, *Graecia capta ferum victorem cepit*, and the Greek language flooded the Latin one with words, loan-translations, syntactic tours and stylistic expressions. Inversely, when the Germanic tribes conquered the Western Empire, they were never able to impose their language in Italy, Gaul, or in Spain, although for centuries they wielded an almost absolute military, political, and economic power, and although even their religion distinguished them sharply from the Romans. What happened was that the Germanic peoples were slowly absorbed, and they adopted in time the religion and language of the conquered. Today we are at a loss to reconstruct the language of the Burgundians, the Goths, the Erules, the Rugians, the Turcilingians, and the Vandals, so thoroughly have they been swallowed up in the Latin-speaking world. It was only when the invaders arrived in overwhelming numbers or destroyed more or less completely the preceding civilization and even the native population, as happened in England, the Rhineland, and Yugoslavia, that the native language was suppressed; and this happened only in relatively peripheral

regions, where the light of Roman culture shone less brightly. It is true that the Arabs were able to assimilate the Roman population in Africa; but, first, this territory was very far from being entirely Romanized (Berber, a pre-Roman language, is still spoken there, and we know Punic was spoken when the Arabs invaded it); and, second, in the time of the Arab conquest Roman culture was in decay—nay, at its lowest—whereas the Moslem world was soaring towards the height of wisdom, learning, and art that have left in Averroes, Avicenna, and the Alhambra monuments of imperishable greatness.

But the most brilliant example of the importance of cultural, and especially of literary prestige can be found in Italy. Florence was only for very short periods the leading political, military, or economic center of the Peninsula. It was not the religious center; it was not always the intellectual center. In military, political, commercial, and economic power, Genoa, Venice, Milan, Naples, Palermo, and even Turin overshadowed it by far. In the domain of scholarship, the glorious universities of Padua, Bologna, Pavia, and Naples undoubtedly surpassed it. Still, the speech of Florence became the cultural language of the whole peninsula and of the three great islands centuries before the political unification of the country in 1870. National unity was the *consequence*, not the *cause*, of the linguistic unification, and this was the result of literary prestige of the great Tuscan writers of the Trecento, especially Dante, Petrarca, and Boccaccio, who all wrote in Florentine, Dante's (but not the others') native dialect. It was merely the beauty of their verses, the charm of their prose that created the Italian language and the Italian nation.

Another example can again be drawn from Italy. From Charlemagne until Dante (800–1300), France was undisputedly the great cultural center of the medieval world, in religion, literature, manners, and custom. Her influence upon Italy, Spain, Germany, and England was enormous. The Italian language preserves deep traces of this. Some of the most common and familiar words, such as *giorno* 'day,' *mangiare* 'to eat,' *arrivare* 'to arrive,' *giallo* 'yellow,' *grigio* 'gray,' *cagione* 'motive,' *ragione* 'reason,' *stagione* 'season,' *trovare* 'to find,' *sovrano* 'sovereign,' *giardino* 'garden,' *viaggiare* 'to travel,' *adagio* 'slowly,' *congedo* 'leave of absence,' *malvagio* 'bad,' 'wicked,' *prigione* 'prison,' 'jail,'

coniglio 'rabbit,' and the suffixes *-iere*, *-iero*, and *-aggio*, which are still very productive today (cf. *aviere* 'member of the air force,' *liniaggio* 'the lynching,' *atterraggio* 'the landing [of an airplane]', etc.), are, without any doubt, of French origin. It was the great personality of Dante which freed Italy from French influences and gave it a language of its own, capable of expressing the great movement that renovated the whole European civilization—the Renaissance. During that period the relation was reversed, and the Italian words and expressions flooded irresistibly all the languages of civilized Europe.

The example of *giorno* is particularly interesting because, as Bärtholi and Spitzer have shown, this word came from Provence to Florence by way of literature. It is now the only word for 'day' in standard Italian and in most Italian dialects.

Sec. 32. *Linguistic Innovations Start from One Individual.* We have seen in the preceding paragraphs that the Italian language was created by Dante: words, expressions, forms created or first used by him were generally adopted and became standard. All great literary languages are the creation of one or a few great authors. Latin would not be as it is without Virgil and Cicero, nor English without Shakespeare and the King James version of the Bible, nor German without Luther and Goethe, nor French without the great seventeenth-century writers. In many cases we can trace the origin of a word or a stylistic fashion to one individual, and fix the exact date of its creation. Cicero created, on Greek models, the words *quālitās* and *mediētās*; they both came into the Romance languages, and the first one into all civilized languages of Europe. It became one of the most common everyday words, an essential tool for the modern man. The Dutch scholar Von Helmont (1577–1644) invented the word *gas* by deforming slightly the Greek word *ζῆλος*, Latin *chaos*: *paradoxi licentia halitum illum gas vocavi, non longe a chaos veterum secretum . . . Gas et Blas noua quidem sunt nomina a me introducta, eo quod illorum cognitio ueteribus fuerit ignota . . .* Every day, in our own time, biologists, doctors, chemists, and physicists invent new words, such as *vitamin*, *penicillin*, *sulfa-drug*, *prostigmin*, *swanium*, *neptunium*, some of which are used after a few weeks by millions of persons. The individual origin of

linguistic innovations is evident in these cases and can easily be proved. But few modern linguists doubt—contrary to the opinion generally held at the end of the nineteenth century—that all types of innovations (phonologic, morphologic, syntactic, stylistic) start from *one individual*, are accepted by others, become fashionable and spread more or less rapidly. It is the initiative, the activity, the fantasy, the creative power of one single man which modifies, creates or recreates language. His social prestige imposes it upon others and gives it citizenship in the language of the group or of the nation. Here again the element of prestige is essential in linguistic change.

Sec. 33. *Conscious and Unconscious Element in Language.* On the problem of *consciousness* in language, as on most linguistic problems, our ideas have entirely changed in the present century; we can almost say that they are just the opposite of what they were. Just as the neo-grammarians, at the end of the nineteenth century, believed that all linguistic changes were *collective*, so they also thought, according to their positivistic mentality, that they were *unconscious, mechanic, inevitable*. Today most linguists (I believe) hold them to be *individual* in their origin and, to a certain extent at least, *conscious, voluntary*. There seems to be little doubt that the effort of learning a language, both for the baby and for the adult, is essentially conscious and that a great amount of attention is concentrated upon the task. Later on, when mastery of the language is attained, speaking becomes, like walking, more and more a habit which we are less and less aware of. But whenever we want to write an important document, to hold a conversation or a speech on which much depends, to compose or read a poem or even the simplest literary prose work, the problem of language emerges before us in all its importance: we study and weigh carefully every word, every form, every sound, lest our pronunciation appear careless, vulgar or dialectal. Even admitting—as is necessary—that the difference between conscious and unconscious is by no means clear-cut, that there is an immense gray zone between these two poles, still it seems that language as a whole belongs more to the first than to the second.

However, many things happen within us which we are not entirely aware of; this is also true in the case of language. An ignorant

French or English speaker will use tenses of verbs correctly without knowing their grammatical value, which he would be entirely at a loss to explain. The same holds true for the aspects or the nominal cases or genders of Russian. The entire structure of language is a thing which has its roots deep in the realm of the subconsciousness, although not of the unconsciousness. A closer investigation of this interesting field is an important task for both linguists and psychologists.

Sec. 34. *Phoneme.* The Prague School, one of the most important contemporary schools of linguistics, was founded by two distinguished Russian exiles, Roman Jakobson (now at Columbia University) and the late Prince Trubetzkoy. This school has developed with excellent results ideas of De Saussure, the Polish scholar Baudouin de Courtenay, and the Italian neolinguist Bărtoli. One of these, the most interesting perhaps from the *semantic* point of view, is the distinction between *sound*, that is, the mere *phonetic matter*, which can be recorded by instruments, and *phoneme*, that is, distinctive *semantic value* of a given sound or complex of sounds, its strictly *functional value* in speech. Let us take, for example, the two sounds *e*, and *ɛ* (closed and open *e*). These two sounds have a semantic value in standard Italian, inasmuch as they suffice to distinguish couples of words: *pesca* 'the act of fishing' is distinct from *pesca* 'the peach' by the mere fact that we have *e* in the first word and *ɛ* in the second; and so is *esca* 'bait' and *esca* 'go out' (subjunctive or imperative, third person), *accetta* and *accetta*, *affetto* and *affetto*. The same is true for French, cf. *dé, daie; clef, claie; jée, jait; the, tait; pré, prêt; épée, épais*, etc., and for German, cf. *Ehre, Ähre; sehe, sâhe; wehren, wâhren*. Now Spanish, for example, also has these two articulations *e* and *ɛ*: but in this language the distinction is merely *phonetic, mechanical, not phonemic or semantic*. It depends exclusively on the surrounding sounds (consonants or vowels), and never distinguishes two words from each other. The vowel *e* is always closed (*ɛ*); for example, in front of *ç* (written *ch*), *l'* (written *ll*), *ñ* and *y*, open (*ɛ*) in front of *x* (written *j* or *g*), *i* and *rr*: *pecho, sello, Peña*, but *teja, oveja, oreja, lejos, peine, seis, veinte, guerra, ferro*. In other words, the two sounds constitute but one phoneme for the Spaniard, whereas they are two phonemes in Italian. Both Italians and Span-

iards have in the same degree the physiological capacity (or rather habit) of articulating both sounds (which the English do not have); but only in Italy, not in Spain, does this distinction appeal to the *linguistic consciousness*, that is, have a real *linguistic* value. The well-known linguist Pos writes in the *First International Congress of Phonetic Sciences*, Amsterdam, 1932, p. 137: "The phoneme is in the linguistic consciousness (conscience linguistique, Sprachbewusstsein), ce n'est pas une chose inconsciente." And Van Ginneken so expresses himself in the same volume, p. 11: "The historical linguists' treated until then the sounds as isolated entities, considering them as dead, if not petrified, quantities [grandeurs périmées, sinon pétrifiées], which was the default of Brugmann and of Streitberg, and became a woe with Herman Hirt; phonetic psychology [viz., phonemics] brought back again man's soul, his intelligence, his will and his feeling in the full history of language, which by love of exactitude had remained entangled in a maze of algebraic formulae [dans un réseau de formules algébriques]." And this, we should add, precisely in the field which was considered the most dead, the most mechanic, the most unconscious: phonetics.

The same distinction (called phonemically *opposition*) is found in Italian for *ó* and *ò*: *cólto* and *còlto*, *bótte* and *bòtte*, *accórsi* and *accòrsi*, *vólto* and *vòlto*, *córso* and *còrso*, *fósse* and *fósse* are different words; so it is also in French (*jausse*, *fosse*; *heume*, *homme*; *hotte*, *ôte*; *paume*, *pomme*; *hausse*, *os*; *saule*, *sole*; etc.). Again in Spanish the difference in articulation is produced exclusively by the surrounding sounds: Spanish *o* is open in closed syllable and also when in contact with *rr* and in front of *x*, *y*, *i*; it is closed in almost all other cases: *gorra*, *roca*, *rosa*, *hoja*, *manojó*, *estoico*, *voy*, *hoy*, but *llamó*, *boda*, *moda*, *pollo*.

The importance of this observation is enormous. For the first time it has been possible to define exactly the number of sounds (now called phonemes) of a language and their reciprocal relationship, to group them rationally in *oppositions*. Only now can we say that the whole of phonetics, formerly separated from the rest of language as "the unconscious part of language," has entered into the domain of consciousness, of semantics, that is, of linguistics proper. With phonemics, it can be said, a

new, flourishing and important branch of linguistics was born.

Another important discovery of the Prague School, partly foreseen by the distinguished American linguist Franz Boas, is the concept of *linguistic alliance* (*Sprachbündnis*), which is closely connected with phonemics. *Unrelated* languages can, by geographical contact, enter into an *alliance*, that is, evolve some common features; this alliance has nothing to do with genetic parentship; it is superposed, and in a certain sense opposed to it, since it tends to form new linguistic connections and thereby to erase the old ones. Russian dialects agree in the use of certain sounds with some Finno-Ugric dialects, with which they are entirely unrelated; Czech is the only Slav language with initial accent, exactly like German; French and Gallo-Italic are the only Romance languages possessing the sound *ʃ*, like German; Castilian has no initial *f*, like Basque. A language can have the same phonemic (or even morphologic or syntactic) system as another language of an entirely different origin. Phonemic, morphologic, or syntactic maps of Europe or Africa or any other region can be drawn, in which the isoglosses of phonemic, morphologic or syntactic phenomena continually cross what we call the linguistic boundaries in the traditional, genetic sense (French, Italian, German, Czech, Hungarian, etc.); nay, they show no connection whatsoever with the latter.

On this point, as on most other points, the Italian neolinguists entirely agree with the Czech school. The two schools have even progressed very much in the same way.

Another concept hinted at by Bártoli and De Saussure, and further developed by the Czech school is the idea of language as a *system*, an harmonious whole, in which all pieces fit together harmonically. Every change shakes the whole structure, introducing other changes in other parts of the linguistic architecture. Here again, a sort of general will and organizing force seems to be constantly at work, supervising, modifying, improving, curing, mending—sometimes, as happens in life, with bad results. Certainly this theory is equally incompatible with any assertion that language is an unconscious phenomenon, unless we admit supernatural forces superior and exterior to man.

Sec. 35. The "Mechanistic" School; L. Bloom-

field. The entire presentation of semantics in this article has been based upon the general assumption that man is a living creature who thinks and feels, and that his thoughts and feelings are expressed through language, although sometimes in a very imperfect way. This general assumption is admitted today by the great majority of linguists of all countries and schools (cf., for example, Terracini, p. 55); nay, the definite trend in recent years has been more and more to stress the emotive and fantastic element in language, to search its interior logical structure, to identify language with the spirit of man. An entirely opposite point of view is held by an American scholar, Leonard Bloomfield, now professor at the University of Yale, and by his followers. His theory is called by himself *mechanistic* (*Language*, p. 33). According to Bloomfield, there is no proof that man thinks or feels; this is an entirely unwarranted assumption, not proved by science. To speak about the meaning of words or forms, to say that a word expresses an idea or an emotion is unscientific: it is metaphysics or theology. What we really see, in fact, is that a certain phonetic utterance of a man (e.g., *give me an apple*) is followed by a certain gesture of another man (he gives the first man an apple). This does not prove that anything has happened in the minds of the two men, that any idea corresponded to the uttered sounds. The reaction of the second man may very well have been of a purely physiological nature, such as the shaking of the arm if it is pricked by a pin or hit by a stone. Language has to be examined by itself, with its own means, without any connections with other sciences (such as psychology, literature, religion, folklore, etc.). It has to ignore completely human thoughts, feelings, ideas, fantasies and superstition, the entire working of the mind. We have to stick exclusively to *facts*, actions, and reactions that we can see, touch, and measure. Nobody has ever seen or touched or measured the human mind, or thought, or feeling, or the meaning of anything. Every utterance containing the words *mind*, *idea*, *meaning*, or the like, is unscientific and has, therefore, to be eliminated. To admit any link of a thinking process between the words of A, "Give me an apple," and the gesture of B giving A an apple (a mental process like: "A asks me for an apple; therefore I will give an apple to him") is to admit an unwar-

ranted, unproven link, and to follow, therefore, an unscientific method. To explain linguistic phenomena through the *meaning* or the *thought* or the *mind* is to fall into circular reasoning, because what we know about meaning and thought and mind we know only through language, and, therefore, our conclusion is already contained in the premise. Language has to be studied in itself and by itself, without any relation to human thinking, just as the works of a clock.

If such a theory were accepted and rigorously followed (which Bloomfield does not do), the field of linguistics would become extremely narrow; every connection between linguistics and psychology would be impossible, and the whole study of semantics completely eliminated. There would be no place for an article like the present one in an *Encyclopedia of Psychology*, for the linguist has to ignore psychology and the psychologist has to refrain from drawing any conclusion from language. But it is not so: Bloomfield's theory cannot be accepted, and this, for several reasons, some of which we will indicate here.

First of all, the argument concerning circular reasoning, for what it is worth, can be likewise used against Bloomfield's theory, or against any scientific theory in any field of science. For, all we know about Bloomfield's theory, or about any other theory, we know through *language* (oral or written), and if the meaning of language cannot be understood by us, Bloomfield's theory cannot be understood either. It is metaphysics to believe that Mr. Bloomfield thinks, or that any other scholar thinks, or that any scholar can understand (through language), study and approve Professor Bloomfield's theory.

In the second place, Professor Bloomfield (like several other scholars of other schools) always considers language exclusively as a *means of communication*, if not of ideas, of stimuli, as the example of the apple shows, which is taken from his book (p. 32). But as we have seen above in several paragraphs, language is also a means of expressing feelings, wishes, fantasies, and was probably in earlier times much more so than now, in our prosaic and business-like century. (It is known that people whom we consider "backward," such as the Indians, Hindus, and Moslems, are much more poetic in speech than the Americans.) It is even likely that language was born this way, from cries of

love, of fear, and of despair, or as an irrepres-
sible urge to expand one's feelings and dreams,
without any idea of a material purpose:

*Ich singe wie der Vogel singt
Der in den Zweigen wohnt,
Das Lied, das aus der Kehle dringt
Ist Lohn, der reichlich lohnt.*

Even in our dry era poets and writers of fiction
write because of an inner necessity, write things
they may never publish, for their own interior
satisfaction, to give vent to feelings which
would otherwise stifle them. This has nothing
to do with asking for an apple. Of the thou-
sands of words which even a modern man
pronounces every day, the majority is spent in
friendly and quite useless chat and conversation
with his sweetheart, his friends, his wife, or his
children.

In the third place, Bloomfield's theory does
not and cannot have any support from a philo-
sophical point of view. No philosopher ever
presented such a theory, and none, I think, will
ever defend it. To call it *materialistic*, as Bloom-
field does (p. 33 of his book), is to distort
completely the sense of the word *materialism*
as it was used up to now by all philosophers,
whether they were or were not materialists.
Karl Marx and Antonio Labriola, to take two
of the greatest thinkers of that school, never
denied or doubted that man thinks, or asserted
that we have to ignore man's thought to be
scientific. They merely said (to put it in Labri-
ola's words) that *ideas do not fall from heaven*,
that is, that they are the product of certain
social, biological, historical conditions in which
man lives. To assert that B is the product and
consequence of A does not mean that we deny
or doubt the existence of B. On the contrary,
it means that we admit that it exists. But, being
materialists, those thinkers considered the hu-
man mind and ideas as an aspect of matter, an
event, and never supposed, as Bloomfield claims
(p. 32) "the interference of some non-physical
factor, a spirit or will or mind," which "is
entirely different from material things and ac-
cordingly follows some other kind of causation
or perhaps none at all." This would have been
entirely contrary to their doctrine of material
determinism.

Or, if we turn to another great radical philo-
sopher, who certainly cannot be suspected of any
sympathy with the abhorred "idealistic" doc-

trines, nor with any "theological" prejudice,
Locke, whose philosophy can be condensed in
the sentence *nihil est in intellectu quod prius
non fuerit in sensu*, we can see immediately
that he never dreamed of denying that there is
something in the *intellectus* (he even speaks
frequently of "ideas"). He merely asserted that
ideas are not innate, that they come to us
through the senses, through experience; which
is, of course, a quite different proposition. The
same holds true, for example, for Hobbes, who
wrote: *Nulla enim est animi conceptio quae
non fuerit ante genita in aliquo sensuum* (*Le-
viathan*, Chapter 1 [*De Sensu*], edition 1670).

In conclusion, for these and other reasons,
Bloomfield's "mechanistic" doctrine of language
must be rejected and semantics remains a field
of invaluable importance for all scholars inter-
ested in psychology and in man in general.

Acta linguistica, Denmark.
Travaux du cercle linguistique de Prague, Czechoslovakia.
Vox romanica, Switzerland.
Cahiers de Saussure, Switzerland.
Bulletin de la société de linguistique de Paris, France.
Année sociologique, France.
Revue de dialectologie romane, France.
Revue de linguistique romane, France.
Romania, France.
Journal de psychologie, France.
Emerita, Spain.
Revista de filología española, Spain.
Revista de filología hispánica, Argentina.
Zeitschrift für vergleichende Sprachforschung, Germany.
Indogermanische Forschungen, Germany.
Zeitschrift für romanische Philologie, Germany.

Archiv für das Studium der neueren Sprachen, Germany.
Zeitschrift für deutschen Unterricht, Germany.

Some of these journals, especially the *Bulletin de la société de linguistique de Paris* and the *Indogermanische Forschungen*, publish reviews of the most important books on general linguistics. The current bibliography is given in a special section of the *Indogermanisches Jahrbuch* (Germany). In America, the need of a journal dealing with linguistic problems from the psychological side is sorely felt; the journal *Word* (New York) aims at filling this gap. Good articles and reviews may be found in several special journals, such as *Classical Philology*, *Italica*, *Publications of the Modern Language Association*, *Modern Language Notes*, *Romanic Review*, *Journal of English and Germanic Philology*, etc. The journal *Language* purposely avoids all articles of this kind.

Special bibliography for each general heading in the article, inasmuch as needed, will be given in the following. Full titles of books will not be repeated.

Sec. 1. Semantics.

- Bréal, M., *Essai*, 6, p. 8.
 Terracini, B., *¿Qué es la lingüística?*, p. 53.
 De Saussure, F., *Cours*, pp. 32 ff.
 Leroy, B., *Le langage*, Paris, 1905.
 Vendryes, J., pp. 8, 10 f., 369 ff.
 Morris, C. W., *Foundations of the Theory of Signs*, Chicago, 1938.
 Carnap, R., *Introduction to Semantics*, Cambridge, Mass., 1942.
 Serus, Ch., *Le parallélisme logico-grammatical*, Paris, 1933, pp. 3 ff.
 Dempe, H., *Ueber die sogenannten Funktionen der Sprache*, Weimar, 1929.
 Hjelmslev, L., *Principes de grammaire générale*, Copenhagen, 1928, pp. 95 ff.
 Bühler, K., *Sprachtheorie, Die Darstellungsfunktion der Sprache*, Jena, 1934.

The philosophers who have more closely dealt with the theory of signs, inclusive of language, are Locke, Leibniz, and above all, the Italian Giambattista Vico. See especially F. Nicolini, *La filosofia di G. B.*, Florence, 1935, pp. 144 ff. The magic origin of signs has been clearly understood by Vico (cf. Croce, *La filosofia di G. Vico*, p. 52); cf. also Vendryes, pp. 367 ff.

Sec. 1. Complex Nature of Language

- Bartoli, M., in *Actes du quatrième Congrès international de linguistes*, Copenhagen, 1936, p. 192 ("if atti linguistici sono infinitamente complessi").

Sec. 2. The Concept of Sign.

- De Saussure, F., pp. 97 ff.
 Vigotsky, L. S., in *Psychiatry*, 2, 1939, pp. 29 ff.
 Pagliaro, A., pp. 86, 113.
 Vendryes, J., pp. 14 ff.
 Terracini, B., pp. 56 ff.
 Bühler, K., *Sprachtheorie, die Darstellungsfunktion der Sprache*, Jena, 1934.

Ogden, C. K., and Richards, I. A., *The Meaning of Meaning*, New York and London, 1944 (cf. especially pp. 511-37, by Crookshank, "The Importance of a Theory of Signs").

SCIENTIFIC LAW IN PSYCHOLOGY, THE CONCEPT OF.—The statement that psychology has a long history but a short past (Ebbinghaus) is attested by the fact that laws in this area are as old as Aristotle, but passing centuries leave unsettled the question of the exact nature of such laws and of the domain where they are presumed to hold. The persistent difficulty in the way of establishing scientific laws in psychology is the problem of determining a specific field of phenomena within which scientific principles are to be established. The main rift lies between mentalism and behaviorism, and involves the body-mind problem in general with its various monistic and dualistic solutions. The present article will first discuss the problem of domain, to be followed by an analysis of various conceptions of psychological law (principles, functions) which follow variant solutions of the domain problem.

The Domain of Psychological Law. For modern experimental psychology the difficulty regarding the proper field for psychology dates back to the disputes between W. Wundt and F. Brentano (1874) regarding the objective or subjective status of sensations; Brentano regarding these as objective (in contrast with subjective psychical "acts"), while Wundt regarded sensory (and other phenomena) as subjective. Later, Mach, Külpe and Titchener found a compromise in terms of the view that physics and psychology start from the same world of experience; but that physics studies phenomena as independent of the observer, while psychology investigates their dependence on observation. However, accepting sensations, percepts, images, ideas, emotions, feelings, etc., as introspectible mental phenomena (Titchener) led to the difficulty of establishing quantitative laws regarding them. The sphere of sensation appeared the most promising for establishing such exactitude. However, it developed that "units" of sensation had to be stated in terms of stimulus units; and "just noticeable differences," presumably purely mental units, varied with the individual observer and from time to time with given stimulus conditions.

Since associated bodily processes are susceptible of quantitative measurement, the inevitable drift of psychology since Titchener has been toward physiology. Hence the development of radical behaviorism (J. B. Watson, A. P. Weiss) has been followed by the importation into psy-

chology of the concepts of reflexology and neurology. At present, one of the major trends in psychology is the initial acceptance of both mental and physiological phenomena as proper areas for psychology, but with the hope of establishing a monism of physiological laws in the end. Thus, Edwin G. Boring proposes a program of research designed to investigate the parallelism between mental and physical dimensions as exhaustively as possible, with the ultimate objective of replacing conscious dimensions by physical ones, achieved by establishing psycho-physical correlations so perfect that dualism would vanish. For the present, dimensions of consciousness cannot be neglected, but their reduction to categories of quality, extensity, intensity, and protensity suggest progress towards simplification. Field and dimensional concepts are used towards this end. The reduction of qualitative differences to quantitative ones appears to be the main stumbling-block to the aim in question. Whatever the neural processes associated with sensations of red and blue, they are not themselves red and blue. Quantification of the qualitative and modal differences between sensations has been sought as follows by J. P. Nafe: Evidences indicate that stimulation involves initial processes of *movement* in non-nervous tissues where end-organs are embedded, as appears quite obvious in the instances of touch, pressure, and kinaesthesia. Pain is regarded as a consequence of intensive pressure, temperature a result of vaso-motor dilation and constriction, hunger and nausea the result of movements of the digestive organs (Boring). Adaptation may be regarded as a consequence of physical equilibrium between stimuli and non-nervous tissues, while evidence indicates that affective and emotional states are pressure patterns arising from bodily movements. Initial patterns of movement generate electrical volley patterns in the nerves, which in their turn result in sensations and patterns of sensation. If it be argued that red, sweet, cold (etc.) still remain unstatable as multiples of a common unit, the reply is that physical sciences too are still dominated by qualitative distinctions between their ultimate elements.

The difficulty of reducing mental to physical events is especially apparent from the point of view of *constitutive analysis*, i.e., where *identification* of mental and neural processes is attempted. The alternative view is that of a psy-

cho-physical parallelism, where the physical aspect of the parallel is favored because of its measurability. From the *causal* point of view the apparent interdependencies between the mental and the physical could more plausibly be replaced by correlations within the latter variable.

The use of operational concepts (P. W. Bridgman) are being introduced with a view of establishing an objective and univocal field for psychology (C. C. Pratt, J. A. McGeech, S. S. Stevens, C. L. Hull, and others). In general, this point of view regards concepts, not as referring to objects (whether mental or physical) but to the operations from which the concepts were derived. Thus, the psychologist, solely occupied with his methods of research and their conceptual results is assumed to be free from ontological concerns regarding the nature of mental events *as such*. Relativism suggests that "things in themselves" in any case depend on relations sustained with other things. The relations rather than the things related become the proper matters for scientific research. When such relations are stated quantitatively they become functions or scientific laws. The efficacy of this attempted escape from ontological concerns may be questioned: The failure of a given process in nature to conform to one law is merely replaced by the failure of various operations to yield the same law.

The ideas of logical positivism (Carnap, Neurath) are also invoked as aids towards the clarification of questions of domain. By translating predicative statements into syntactical form, having to do with the *form* of the assertion and not its material *content*, there emerge a variety of syntactical languages of science; which, like operationism, are assumed to avoid metaphysical questions. It is proposed that unity be achieved among syntactical languages by regarding the language of physics as basic for all of them. The translation of psychological statements into "equipollent" physical ones is thus designed to attain an objective and verifiable psychology, as when anger is stated in terms of physiological rather than introspective data (Carnap).

Hormic and Gestalt points of view are quite opposed to the tendencies sketched above towards homogeneous domains for psychology, whether physical, physiological, methodological, or linguistic. The hormic school (McDougall,

Freud) accept both bodily and mental components of behavior and seek to find their integration in terms of teleological principles. The earlier functional school (James, Angell, Ladd) sought a similar integration in terms of the concepts of adaptation and survival. The latest development of these trends occurs in current studies of levels of aspiration and the effects on such levels by barriers, field-limiting factors, personality traits, previous experience, etc. (See *Levels of Aspiration*.)

The *Gestalt* movement, particularly under the influence of Köhler, approaches the domain problem as follows: After making an initial distinction between physical and physiological realms (both being transphenomenal and inferred) and the phenomenal world of experience, Köhler seeks to find explanations for observed connections between phenomenal experiences in terms of hidden principles of functional dependence in the physiological (neurological) realm. Between these two realms, each conceived as an organized field, principles of isomorphic resemblance are to be found—segregation, continuity, enclosedness, order, gradience.

Conceptions of Psychological Law. We have now to sketch the main conceptual forms of psychological law developed in the various views regarding the proper domain for psychology. In the material sciences laws are statements of the quantitative invariant relations (functions) which hold between two or more variables. For behavioristic systems, since subjective data are excluded, the problem is to discover what functional relations (*f*) hold between measurable stimulus (*S*) conditions and response (*R*) variables. If under given *S* conditions the *R* consequences were always the same, *f* principles of exact form could be established. In psychology this ideal simplicity is never attained even with the simplest reflexes (Sherrington). Hypothetical intervening variables are introduced to account for observed variations of *R* when the *S* conditions are fixed. In fact, certain subjective mental states of the subject may be regarded as intervening variables in this sense. The behaviorist, of course, will tend to employ intervening variables inferred from the *S* or the *R* factors. The factors thus inferred will usually be neurophysiological concepts. Failing demonstrative evidence of the existence and identity of the latter the behaviorist posits hypothetical ones (K. W.

Spence, C. C. Pratt, E. C. Tolman, and C. L. Hull). Such intervening variables serve the heuristic purpose of breaking down the intricate network of relations between S and R variables into simpler component functions. E. C. Tolman and C. L. Hull are at present the accredited spokesmen for this point of view.

Tolman recognizes two main classes of independent S factors: environmental and individual difference variables. The individual variables modify the effects of environmental variables on resultant behavior. Environmental and individual difference variables (independent) are integrated with the R variables (dependent) by a general function f_1 . However, this basic f_1 function may be established gradually by assuming hypothetical and less general intervening constructs of two types: f_2 variables which mediate between the independent variables and F_1 , and f_3 functions which hold between f_2 and the dependent variables R. These intervening constructs begin as hypotheses but are ultimately defined experimentally. Thus, in Thorndike's studies of animal learning, the law of effect is an f_2 function uniting the independent variables and the basic f_1 function of "bond formation." Tolman makes use of such variables as demand, appetite, differentiation, etc.; and considers that Lewin's topological vector concepts lead to the best understanding of the f_3 functions; which, since their operation immediately precedes R, express the joint action of earlier factors.

C. L. Hull notes that since our present knowledge of behavior is confined to relatively coarse segments of behavior, our knowledge of behavior is and will remain *molar* for some time to come, that is, will be inexact. Hence, psychology, like physics, resorts to the use of hypothetical entities to bridge regions not directly observed. Hull notes the similarity between the physicalism of the Vienna positivists and the behavioristic approach. Thus, felt anger is an objectively unobserved intervening variable between the situational causes and the attendant organic responses of anger. The modern behaviorist thus appears to use an introspected datum to identify the *kind* of process under investigation, as the physicist might use the quality red to signify the presence of light vibrations of a certain wave length. Hull's hypothetical intervening variables—habit-strength,

afferent impulse, drive intensity, reaction-potential magnitude—appear to be more objective than some of Tolman's (demand, appetite). Such terms may appear as masked labels for psychological terms, as when Hull conceives *need* in one situation as the number of hours of food deprivation. However, this term is treated as hypothetical until experimental observation has indeed shown that a definite function holds between hours of food deprivation and behavior, justifying the definition of need in terms of the former. In both the systems of Tolman and Hull the operational value of these schemata are stressed, and their use in concrete research is pursued energetically. Other psychologists (E. Brunswik, C. E. Buxton, and others) have adopted similar schemata for psychological research.

There are psychologists, however, who consider that the establishment of S-R functions does not require the use of intervening variables, not even physiological ones (H. Woodrow). The concept of "need" (in Hull's sense) appears to simplify research by confining observation to the effects on behavior of variations in the S condition of food-deprivation. The function holding between such deprivation and the number of times (behavior) an animal crosses a barrier may be investigated *directly*. To assume an intervening food-getting "need" is redundant, since such need is defined in terms of the number of crossings. Similarly, we do not need to know the neurological correlates of memory or intelligence in order to measure them in S-R terms.

In Gestalt psychology scientific laws are statements of functional relations holding between wholes: the whole subject, the whole situation, the whole response. For all three of these there are emergent whole properties (Ehrenfels qualities) not accounted for from observations of fractionated parts of them. For the Gestaltist (Wertheimer, Koffka, Köhler, Lewin) the aim of psychology is to discover principles which operate in the same way in various whole areas of phenomena; as when the principles of similarity, closure, pregnance, etc. function in the areas of perception, learning, recall, problem-solving, goal-seeking, etc. Or, taking one of these principles, research seeks to determine how it operates in some phenomenal area and in the associated neurological processes. Such principles appear to play a role in psychology sim-

ilar to that of certain principles in material sciences, as when the principle of inertia appears as an explanatory concept in all phenomena of movement, or where the concepts of attraction and repulsion are invoked in molecular chemistry. Such general principles become general laws or functions when stated quantitatively. There is a similarity of meaning and use which *Gestalt* psychology makes of such principles and the intervening variables of Tolman and Hull; except for the insistence of the Gestaltist that functions hold, not between atomic variables, but between configured wholes which are not to be fractionated beyond sub-wholes. However, the F_1 function of Tolman, when attained, would be a genuine *Gestalt* principle. The dispute between the two schools would then be a methodological one—the Gestaltist contending that an isolated S factor has different results than the same factor in a configured whole. In actual practice, since the neo-behaviorist varies one factor at a time, not when it is "alone" but when other S factors are present, the S situation may operate configurationally (dynamically) as demanded by the Gestaltist; and observation could not fail to reveal altered effects on behavior when a given S condition occurs in a new combination with others. The question which remains is whether or not the altered behavior resulting from variations in the S setting can be stated as a quantitative resultant of the S factors considered separately. The analyst in psychology tends to support the view that the general f_1 function is the quantitative resultant of simpler S-R functions; and the Gestaltist tends to deny this. Research findings alone can decide this issue: so far, both views claim experimental substantiation.

In Lewin's system an environmental field (E) interacts with an organized subject (P), and the resultant behavior (B) emerges as a whole from the E-P setting; where B, P, and E are psychologically conceived. For Köhler in particular the task of psychology is to discover hidden principles of functional dependence in the physiological sphere which correspond isomorphically with connections observed in the phenomenal sphere, where both spheres are conceived as macroscopic fields exhibiting *Gestalt* properties. These isomorphic principles are essentially principles of similarity between the two fields. Thus, when the observer sees a segregated object phenomenally, a segregated

process occurs in the visual cortex. Theoretically, as in Boring's system, the identification or perfect correlation of mental with physiological strata of reality might follow the discovery that all relationships between the two strata are isomorphic. Köhler questions the attainment of this state of affairs because isomorphic principles of phenomenal and cortical processes appear to be confined to macroscopic events (compare Hull on *Molar* psychology). There appears to be no way of extending principles of isomorphism (say) to colors and *microscopic* (chemical) processes in the visual areas.

SOCIOMETRY.—Sociometry, as a school of thought, was started by the work of J. L. Moreno, M.D., and gained its greatest impetus through his original development of new methods of exploration and analysis useful to social scientists in any field. (His sociometric contributions should be studied in conjunction with his equally important and fruitful work in psychodrama and sociodrama.)

Sociometry is the study of the interrelation patterns existing between people. It is not concerned with official relationships but with the actual psychological components of their existing interactive relationships. It aims to uncover the psychological geography of society, the dynamic interpersonal structures which are the base for all other societal phenomena—the structure in which the latter are imbedded and

carried. It contends that to study the latter apart from their locus is futile.

Sociometry views the feeling process of attraction and repulsion between people as *tele*, dependent upon *both* individuals, even though the flow of feeling may be at an infra level from one individual, or may be incongruous, at different levels of intensity and mainly positive and/or negative from either individual. (It thus, of course, departs from the notion of affect as being an individual projection.) It discloses and emphasizes the interindividual nature of society and explicitly demonstrates the interdependence of mankind in the psychological geography of his society. It insists that a science of society must have knowledge of the actual psychological structure obtaining among its peoples and within all groups.

Consequently, from a sociometric viewpoint, the personality of a given individual must be seen in the midst of his interpersonal relationships, as the center of a *social atom* made up of his numerous tele relationships with other individuals; these other individuals in turn are seen to be linked through their social atoms with yet other persons more distant from the given individual psychologically, but through his indirect linkage with them he may exert (or receive) influence, and his "personality" be felt (or respond). The psychological roadways that cross this social atom may comprise many psychological *networks* which may have a bearing upon the milieu in which he as a person acts and is to be understood. His role in the group can be defined specifically through these sociometric data. Similarly he may be found a focal point of *cleavages* of an interpersonal sort. Such dynamic social facts are seen to be essential for study of personality. (Words in italics are sociometric terms first used by Moreno to describe the findings.)

The main instrument making for progress of sociometric knowledge has been the sociometric test devised by Moreno. His sociodrama and psychodrama, however, have illuminated many areas where exploration at deeper levels is needed. The sociometric test discloses the feelings which individuals have in regard to one another in respect to membership in the group in which they are at a given moment (ideally all groups in which they are members). (It is often described erroneously as a test of friendship constellations; a few sociometric tests of

friendship have been made, but only superficially; the latter are difficult to make, whereas other groupings have more definite goals and their outlines can be more readily defined.) It is an action test. Intrinsic to its validity also is the fact that it is so constructed as to enable the subject to be an active agent in his *own* behalf. (For example, a child in school is invited to choose those other schoolmates whom he wants to sit beside in the same classroom.) The criterion of the test is the nature of the group it is to serve, and accordingly it alters with the group. (For example, in work sections in factories the criterion would be the particular task involved.) In all cases the criterion for choice must have explicit meaning for the subject and offer him the specific opportunity to give information for reconstruction (or retention) of the situation in which he is. The procedure is open and the results are put into operation to the optimal satisfaction of all members of the group. There is thus brought to light the psychological position of every member and the composition of the group's structure as a whole at a particular time. By periodic testing, the changes in structure can be traced, followed, and evaluated.

The *emotional expansiveness* or *tele range* differs from individual to individual and presumably could be affected by the spontaneity of the individual, similarly as other aspects of his life are affected by this factor. In early childhood, "the *s* factor is an active agent in behalf of the infant long before intelligence and memory develop," but "there comes a point . . . when intelligence and memory take the lead and the *s* factor is forced more and more to be subservient to them." (Quoted from J. L. and F. B. Moreno, "Spontaneity Theory of Child Development," *Psychodrama Monographs*, No. 8.) This is not in conflict with the writer's finding that the individual choice expression, "his emotional repertoire," shows no significant change at an age level approaching adulthood. It may well be that the *s* factor by this time is itself relatively constant in its influence; at earlier age levels it may be progressively reduced as the child grows older and is himself compelled to behave in stereotyped patterns in accordance with what the culture dictates.

Sociometry discloses that the psychosocial structure of groups is directly related to the

way in which the group functions—that the conduct of individuals thrown into association with one another for whatever given end is explainable in the light of the psychosocial structure of that group (both within itself and towards other groups). It reveals that individuals generally seek to relate themselves to other individuals regardless of the response towards them made by other individuals with whom they are in contact. Moreover, attitudes exhibited in conduct are found to be related to such social relationships as the individuals have at the time they show particular attitudes.

When individuals are allowed to group themselves according to the positive and negative tele existing among them, the structure which results is not merely the genuine psychosocial structure of that community: it is the structure which represents the alignment of the members towards one another *because* of basic needs which find fulfillment through specific other members in that community. It makes apparent the actual dynamics of social change and the avenues along which it is taking place.

In such a structure the overchosen individuals cannot be described and dismissed as "popular" persons: they are not popular in any superficial sense. They are found to be the protagonists of the needs and desires of large numbers of the population—sufficiently effective protagonists to draw choice on a sociometric criterion or on several sociometric criteria. They are the members who are most wanted participants and who have earned this choice status because they act in behalf of others with a sensitivity of response which does not characterize the average individual in the community (chosen to an average extent). They are found to be individuals who see beyond the narrow circumference of their own personal needs into the wide range of needs of their fellow-citizens. They are the individuals who go farthest in relating themselves to others and in translating the needs of others into effective outlets. And when the actual psychosocial structure is allowed to find expression, the community is found to produce many varieties of leadership—varieties which represent the manifold, diverse needs of its many interacting participants. Similarly many varieties of isolation (individuals unchosen) are revealed.

Thus to implement democratic practices fully,

sociometric techniques would appear indispensable. Through their systematic use, it is premised, man could build a psychosocial structure of society which would function at the actual plane of his own ingenuity, social insight, and spontaneity—that is, a society in which there will be no cleavage between the overt manifestations of group life and the network of interpersonal relationships existing between the participants. Sociometry, as a movement, is developing rapidly in this direction. Its fields of application are closed and open communities, families, schools, churches, factories, etc.

The following quotation is representative of Moreno's statements on sociometry:

"A true therapeutic procedure cannot have less an objective than the whole of mankind. But no adequate therapy can be prescribed as long as mankind is not a unity in some fashion and as long as its organization remains unknown. . . . A number of scant proofs have been uncovered which indicate that such a unity of mankind does exist. Its organization develops and distributes itself in space according to a law of social gravity which seems to be valid for every kind of grouping irrespective of its membership. . . . These tendencies may become apparent on the surface in the relations of individuals or groups of individuals as affinities or disaffinities, as attractions and repulsions. These attractions and repulsions must be related to an index of biological, social and psychological facts, and this index must be detectable; these attractions and repulsions or their derivatives may have a near or distant effect not only upon the immediate participants in the relation, but also upon other parts of that unity which we call mankind. The relation which exists between the different parts may disclose an order of relationships as highly differentiated as any order found in the rest of the universe."¹

SPEECH PATHOLOGY.—I. THE FIELD OF SPEECH PATHOLOGY. Psychologists as a professional group have often failed to appreciate the close relationship which exists between their own field and that of speech pathology. Although the majority of the membership of the American Speech Correction Association have had psychological training, and professional membership in this organization is not granted without a thoroughgoing academic and clinical preparation in psychology, there is no affiliation or close association with the various psychological groups. This misunderstanding is especially unfortunate, since the majority of problems met in speech pathology are usually diagnosed and treated through the application of methods well within the scope of clinical psychology. Speech pathology is at present oscillating between the fields of psychiatry and speech education. It may finally come to rest in clinical psychology.

Speech pathology has experienced a remarkable growth in the last fifteen years. College and university speech clinics are now offering their services in all but a few states. Special classes in corrective speech are conducted in many large school systems, and special speech correction teachers have been subsidized by some of the states to serve small towns and even rural schools. Teachers' colleges are training elementary school teachers in the recognition and prevention of the speech defects and disorders. Child guidance clinics often include a speech pathologist. Many hospital speech clinics exist in the United States, although they do not dominate the field of speech pathology as they do in England and on the continent. Private practice, usually associated with pediatrics, or otolaryngology, has also shown a steady growth. The number of charlatans in the field has decreased rapidly, due to the influence of the American Speech Correction Association and its voice, the *Journal of Speech Disorders*, abstracts of which regularly appear in the *Psychological Abstracts*. Organized programs of research are being carried out in many of the major universities, and the quality of this research is steadily improving.

As in so many other fields, a good deal of controversy exists. Agreement is fairly general so far as etiology and therapy of the articulatory (Dyslalia) and voice (Dysphonia) disorders are concerned. Stuttering (Dysphemia)

and cerebral palsy speech (Dysarthria) and aphasic speech (Dysphasia) present problems much more complex, and many different theories and therapies prevail.

The nomenclature of speech pathology, once so cluttered with Greek and Latin combinations that seven or eight unpronounceable synonyms were used to designate a particular symptom, has shown an unmistakable trend toward simplicity. For example, an articulatory case whose dyslalia manifested itself in defective *r*, *k* and *s* sounds was formerly said to possess rhotacism, kappacism and sigmatism. A monograph by Ogilvie¹ compiled the various labels and definitions and helped greatly to establish a common usage.

Classification of the speech disorders is based either on etiology or symptomatology and the latter seems to be becoming dominant, probably because categories of symptoms can be more discrete than categories of causes. When such an influence as imitation can produce several very different speech disorders, it has little classification value. At the present time both etiologic and symptomatic classifications are commonly used. *Stuttering* (Dysphemia) refers to the functional disorder characterized by abnormal hesitations, repetitions, prolongations and the associated struggle and avoidance reactions which interrupt the rhythm or fluency of speech. *Articulatory* disorders are commonly divided into *Dyslalia* (functional) and *Dysarthria* (organic). Both are characterized by sound substitutions, omissions, insertions or distortions. Lipping, lalling, baby talk, and a multitude of other terms are used to designate different patterns of defective sounds. The *voice* disorders (Dysphonia) refer to defective pitch, intensity or timbre of phonation. *Aphasic speech* (Dysphasia) designates the disorder characterized by difficulty in the perception, formulation or expression of speech.

Many speech disorders fall into several of these classifications. The speech of cleft palate, foreign accent, spastic and aphasic cases usually involve both defective articulation and phonation. Despite these difficulties, the general practice of the speech pathologist concerns itself with the speech disorders as so defined.

II. DYSLALIA (FUNCTIONAL DISORDERS)

Symptomatology. Individuals with Dyslalia have defective speech sounds, and their errors may be classified as substitutions (*tandy* for *candy*), omissions (*no* for *nose*), insertions (*gareen* for *green*), and distortions such as the slushy *s* and *z* sounds so characteristic of a lateral lisp. Approximately 79 per cent of all speech defective children have such consonantal errors, and more than one defective consonant is usually found in any given case. The patterning of these multiple errors frequently has implications for diagnosis and therapy. In *lalling*, the majority of the substitutions and distortions are often due to inactivity of the tongue tip in the production of the speech sounds. Hard of hearing children frequently confuse such cognate consonants as *f* and *v*, *k* and *g*, or *s* and *z*. The most frequently mispronounced consonants are the *s* and *z*, *d* and *f*, and the various *r* and *l* sounds. Sound substitutions are the most frequent type of error with distortions, omissions and insertions following in that order. Errors are most frequently found in the final position, and least frequently in the initial position of the word.

Since *Dyslalia* arises out of the early speech patterns of childhood and seldom appears spontaneously (except in brain injury cases or as regression phenomena in adolescent children), the etiological factors usually involve developmental retardation. Low intelligence usually reflects itself in dyslalia, but it is probably not a direct causal factor, since many aments attain a mental age of seven (when normal children have good speech) and still are badly dyslalic. Recent studies have shown that severe illnesses at the time children normally learn to talk, birth injuries, slow physical growth, and high-frequency deafness, are common factors in producing dyslalia. Environmental factors such as too much isolation, over-anticipation of the child's needs without requiring speech, unreasonable parental speech standards or demands, imitation of defective speech, parental fostering of infantile behavior, improper methods used in teaching the child to talk or in penalizing his infantile errors are all important mal-influences in dyslalia.

Organic abnormalities of the palate, tongue, teeth, lips and jaws as etiological factors are

¹ Ogilvie, M., "Terminology and Definitions of Speech Defects; Teachers College Contributions to Education," No. 859, 1942, 300.

treated by most recent texts in speech pathology with some caution. Backus declares, "Structural anomalies in the mouth do not always produce articulatory defects." Berry and Eisenson say, "Too often, we believe, the cause of articulatory defects has been assigned to the oral articulatory organs." West, Kennedy, and Carr refer to a mysterious x-factor to explain why one child with a severe dental or oral abnormality will have dyslalia while another child with the same structural defect has perfect speech. Van Riper points out that feeble-minded children with organic abnormalities seldom learn to compensate for them so as to produce the speech sounds in unusual but acoustically adequate ways, but that normal children with good speech standards and instruction can do so.

Poor motor coordination is often cited as a cause of dyslalia, and recent research seems to corroborate this belief. Dyslalics are below average not only in tongue strength and movement control but in the larger motor skills. Both speed and accuracy seem to be affected. Palmer and Osborn's research is especially promising in that they found statistically significant differences in tongue strength (pressure) between normals and dyslalic speech defectives.

Another etiological factor, largely unexplored, involves perceptual deficiencies. The dyslalic case seems to lack the ability to analyze words into their component sounds, and he also finds difficulty in synthesizing or combining sounds to form new word-wholes. This factor, which seems vital to the self-correction which the dyslalic must master to overcome his speech problem, has been investigated only through auditory memory span tests, and the research has been inconclusive.

Therapy. The treatment of dyslalia varies with the severity of the disorder. Younger children with few defective speech sounds are often treated in large groups, emphasis being placed on the identification of the consonants, their acoustic features, and manner of production. Strong stimulation and the analysis of word-wholes into their sequential components (vocal phonics) are employed. Errors are made vivid, yet penalty is avoided. Public school systems which have instituted such programs of speech improvement in the elementary grades produce few adult dyslalias.

Therapy for older or more severe dyslalia

cases often requires much more than this simple teaching of new speech sounds. Attitudes of shame and embarrassment, retreat reactions which affect the entire personality, compulsive plunging into unnecessary errors, transitory auditory amnesias, all these problems and many others tax the clinician's ingenuity to the utmost. Not only must new sounds be taught but old ones untaught. Words are configurations, melody wholes, and when a sound lasting one-thirtieth of a second is the only defective feature, some difficulty is experienced in replacing it.

Upon a background of consonant identification and word analysis, the speech pathologist usually concentrates his therapy on a single defective consonant. Auditory perception of the differences between the correct and incorrect sounds is stressed. Powerful stimulation with the isolated sound is given until it temporarily dominates the dyslalic's consciousness. Then the isolated correct sound is taught. Several methods are used: the modification of known sounds, auditory stimulation, phonetic placement of the articulatory organs, and the moto-kinesthetic method. The newly acquired sound is then strengthened through simultaneous talking and writing procedures, or the use of rhythms or melodies, until it is being produced correctly and automatically in isolation and in nonsense syllables. Then, through reconfiguration devices and other techniques involving preparatory sets released by a sudden signal, the newly acquired sound is incorporated into familiar words. After these are mastered under conditions of speed, or emotional excitement, the therapy proceeds to the habituation of the new sound. Negative practice (Dunlap's Beta hypothesis), the use of nucleus situations in which errors are checked or self-penalized, and the cancellation of failures are used in this habituation.² Drill is minimized in modern speech pathology and the new sound is incorporated into meaningful communicative social situations as quickly as possible.

III. STUTTERING (STAMMERING)

Symptomatology. When stuttering begins, usually at the pre-school age, the symptoms consist primarily of automatic effortless repeti-

² See texts by West, Kennedy, and Carr, Backus, Nemoy, and Davis, Van Riper, Froeschels, and Berry, and Eisenson, for details of therapy.

tions of syllables or equally easy prolongations of the initial sounds of words. These, the primary symptoms, occur usually at the beginning of communication and under conditions of communicative stress. The child seems unaware of these breaks in his fluency at this stage. If they become unpleasant through their frustrating of important communication or if the child's associates penalize them or bring them to his awareness, he begins to react to them by struggle or avoidance. Fears of words, sounds, or speech situations develop, and pronounced anxiety states occur. The child adopts tricks and devices to avoid, postpone or time the speech attempt, and these become ritualistic habits of approach to the feared words. The struggle to release himself from the automatic clonic repetitions or tonic prolongations results in hard contacts of the lips, tongue-teeth, tongue-palate, or ventricular folds. These contacts are accompanied by force so great as to precipitate tremors of the organs involved. Since they interrupt the air stream necessary for speech, much of the struggle involves the breathing apparatus which commonly demonstrates (in this secondary stage of stuttering) pronounced anomalies. When all these reactions are supplemented by interruptor devices, retrials, and disguise reactions, the total abnormality becomes bizarre indeed. Severe stutterers are penalized socially, academically and economically, and profound personality deviations are frequently found. According to most researches, one per cent of the school population stutters, and the frequency does not decrease with age. More males than females stutter and the ratio is approximately six to one.

Etiology. Most of the research on the etiology of stuttering has been indecisive, probably because of the theoretical bias of the investigators, and there are almost as many theories concerning the nature and etiology of stuttering as there are stutterers. No single cause of dysphemia is known. Instead, there seem to be certain predisposing factors such as stuttering heredity, birth injuries, severe fevers during the speech-learning period, physical and emotional trauma, a shift of handedness, emotional conflicts manifested through excessively critical or anxious parental attitudes focussed on the normal hesitations which most children show. The precipitating causes are of infinite variety but they usually reflect some type of emotional

conflict centering on speech. Organic abnormalities of the speech organs have no direct bearing on etiology.

Therapy. Beginning or primary stuttering is treated by the majority of speech pathologists in the same fashion. The disturbing environmental influences are identified and removed. Frustration is avoided and penalties are discarded. Since primary stuttering usually comes in waves, the good periods are used to foster much speech, and the bad days are arranged so as to entail a minimum of communication. The child's security is enhanced in every possible way. Excitement and emotionality are minimized. Periods of speech play are instituted and these consist of speaking in unison, of rhythmic sentences, under conditions of relaxation, of echo speech, of combining speech with large trunk and limb movements. The parents are instructed to speak to the child more slowly, rhythmically and simply, and less frequently. Interruptions, speech competition, demands for speech exhibitionism, the confession of hurt or guilt are avoided. In short, environmental influences leading to speech hesitancy are removed, and a new regime which fosters fluency is instituted. The primary stuttering symptoms are not treated directly.

Treatment of the secondary type of stuttering (that marked by avoidance and struggle reactions and habits, by fears of words and situations) varies with the speech pathologist and the individual with whom he is working. An excellent historical study of the methods used in treating dysphemia is that by Klingbell, and Hahn has surveyed present-day therapies. Hypnosis has been used successfully in exploring past conflicts, but extensive experiments in post-hypnotic suggestion have shown only temporary results. Psychoanalysis has effected some "cures," but all therapeutic regimes have had occasional success. Two major types of therapies, both symptomatic, are prevalent. In the first, relaxation, suggestion, and distraction are used to prevent the occurrence of stuttering. The case is convinced that he can talk without "blocking," and his confidence is built up by proceeding from easy to difficult situations until fluent speech is achieved. In the second type of therapy, the stutterer is encouraged to stutter but to vary the type of symptoms until he has learned to stutter with a minimum of effort, interruption or abnormality. The advantage of

this type of therapy, according to its exponents, is that it fosters better mental hygiene and prevents relapse. Feared words and situations are faced directly. Avoidance and disguise reactions, which precipitate relapse, are unnecessary when the stutterer can control his speech disorder to such a degree that society will not notice or penalize it.

Both of these major types of therapy are supplemented by other techniques aimed at building up the stutterer's security and solving his conflicts. Most speech pathologists also employ other supplementary methods such as breathing rituals, rate control, simultaneous talking and writing, and rhythmic timing, which reflect their theoretical bias. Therapy based on etiology alone has seldom been successful, since stuttering has a perseverative character which provides its own precipitating factors. The problem is very complex, and although excellent results are reported by many clinicians, no one method for treating this disorder has found general acceptance.

IV. VOICE DISORDERS (DYSPHONIA)

Symptomatology. Dysphonia may involve pitch, intensity or timbre, either separately or in combination. Thus the *false* voice is not only abnormally high in pitch, but it also possesses a characteristically peculiar quality. A monotone, speaking at the lowest note of his pitch range, may also have so weak a voice as to interfere with communication and may call attention to itself. On the other hand, a *denasal* (adenoidal) voice may demonstrate no abnormality of pitch or intensity. The dysphonias most frequently treated by the speech pathologist are *aphonia* (loss of voice), *rhinolalia* (excessively nasal or denasal speech), *false* voice or too highly pitched voices, *monotones*, *hoarseness*, and *guttural* voices. *Cleft palate speech*, which presents a common problem to every speech pathologist, consists of a voice defect (excessive nasality) and an articulatory defect, since most of these cases not only emit the consonants through the nose, but also demonstrate many sound substitutions, omissions and distortions. Therapy for cleft palate speech (*uranischolalia*) uses techniques taken from both the fields of dysphonia and dyslalia, and in addition, special rehabilitation in strengthening the palate and directing the phonated air stream through the oral port is stressed.

Etiology. The causes of dysphonia are both organic and functional. Nodules on the vocal cords, inflammation of the membranes, diseases such as tuberculosis or laryngitis, cancer, injury to the nerves controlling the larynx or palate, and many other organic causes can be cited. Poor hearing frequently results in compensatory disorders of intensity, pitch or quality. Interrupted or abnormal sexual development often reflects itself in defective phonation. Despite all these factors, the majority of voice defects are probably of functional origin. Overstrain and abuse of the voice, imitation, poor training and emotional conflicts are the common causes of dysphonia.

Therapy. The treatment of voice disorders consists primarily of removing the etiological factors involved. Treatment of the symptoms is often necessary since habits of defective phonation may persist long after the original cause has ceased to exist, but voice retraining alone is seldom satisfactory. Hysterical aphonia or the nonexpressive monotonous voice are often treated entirely through placebos, suggestive shock, hypnosis, or similar psychiatric techniques. Strained, strident and false voices have often responded to relaxation techniques or to mental hygiene.

In other cases, careful retraining is necessary. Since the habitual pitch levels of these cases are often far out of line with their optimal pitch level rehabilitation involves ear training, devices to raise or lower the pitch such as stroboscopy, and habituation. Breathing retraining is often useful in establishing new habits of phonation. The vowels are usually the vehicle for this therapy, and the worst vowel is often used as a nucleus for retraining. Reading or memorized passages are worked over through the use of pre-scored material until adequate voice is achieved. Then through the use of nucleus situations or rehearsal, the new voice is gradually brought into daily communication. Often a certain phrase, or humming, or vocalized throat clearing is used to precede speech attempt, so that the case may "find" the new voice and key his conversation to it.

Other disorders which are frequently treated by speech pathologists are those of foreign accent with its peculiar melody, stress and inflection patterns. As in cleft palate speech, articulatory reeducation is also necessary. Occasional cases of *ventricular* (false vocal cord) phona-

tion, or *diphthongia* (two-toned phonation) are treated, and laryngectomized patients are taught to use the artificial larynx or esophageal speech.

V. APHASIA (DYSPHASIA)

Symptomatology. Aphasia represents an extreme degree of the difficulty in symbolic formulation and expression which characterizes dysphasia. Aphasics frequently manifest aphonia and articulation difficulties but their greatest problem is in comprehending, formulating and expressing meaningful material. Reading, writing and speech are commonly affected, but disturbances are also found in such representative activities as telling time and perceiving the functions of tools. Essentially, aphasia is a syndrome, a symptom complex, and the symptomatology varies so greatly from patient to patient as to make analysis and classification very difficult. Pronounced behavioral changes occur. The aphasic is often addicted to periods of weeping or rage, and irritability is excessive. Amnesia for names of objects, qualities, conditions or relationships is common. Apraxia and agnosia frequently make the clinician's task more difficult. Aphasics show marked perseveration both in speech and other language functions, repeating the same nonsense syllable or writing the same word over and over again. They occasionally show no understanding of their linguistic errors and become enraged when their auditors show no comprehension of their mutilated jargon. Their auditory memory span is markedly decreased.

The terminology used in reference to aphasia is difficult and confused, but the classification of Weisenberg and McBride seems to be finding wide acceptance in the field. They classify the dysphasias into four categories: the *predominantly expressive*, the *predominantly receptive*, the *expressive-receptive*, and the *amnesic* types.

Etiology. While some hysteric cases of dysphasia have been reported, the vast majority of them result from injury to the brain cortex, usually in the hemisphere on the side opposite the dominant hand. Efforts to localize the different types of aphasia in terms of trauma to specific areas of the cortex have not been entirely successful. The greater the injury, the more complex the symptomatology. Infectious diseases such as syphilis, encephalitis, or meningitis, and vascular disturbances resulting from

hemorrhages, thromboses or embolisms are common causes of the cortical damage. Many soldiers suffer head wounds which produce dysphasia, and tumors present another common cause.

Therapy. While no one can predict the prognosis for speech rehabilitation of aphasics with certainty, many of them have shown remarkable recovery when exposed to speech therapy. Some of the improvement may be due to amelioration of the psychological trauma present when the case was first seen; and some may be due to the development of other cortical areas (e.g., those in the opposite hemisphere) or fibers as functional units subserving the language processes. Some recovery occurs as the result of medical and surgical treatment. The speech pathologist feels that his function is to facilitate all of these by providing a systematic program of language recovery.

In retraining the aphasic many techniques are employed. A shift of handedness is often instituted, with manual activities being practiced in conjunction with vocalization. Training in articulation is often necessary to show the patient the repertoire of speech sounds he has lost, and to train him to use his speech muscles voluntarily. Imitation through mirror-work and even manipulation of the organs of speech is necessary. In one case the blowing of cigarette smoke was the only way in which the voiceless consonants could be taught. It is also necessary to teach some inhibition, not only of the wild emotional states which interrupt therapy, but also of the echolalia which hampers the acquisition of new vocabulary. Objects or activities which had special significance are used to evoke new words and the symbolic representation is reviewed frequently in order to fix this. Pictures or printed material are of far less value. Once a word is acquired it must be used in as many meaningful situations as possible. Rhythmic activities, pantomime and gestures are taught and combined with speech. With the receptive types of aphasia, it is necessary to proceed in the same way as we would with deaf children learning to speak. Associations must be built up between tactual, visual, and kinesthetic experiences and the auditory presentation of a word. Lip reading and even Braille material is used to open the doors to the patient's comprehension.

Motivation is of extreme importance, and the

periods of treatment should be short, interesting and end with success. The mental hygiene of the patient always needs careful attention. Since the clinician-patient relationship is always close, it is necessary to wean the latter psychologically before the association is terminated. This is especially important since many aphasics finally will learn to speak well when the clinician is present but at no other time. Increasing audiences and delegation of therapy often help to solve this problem.

of science are integrated in the development of scientific bodies of knowledge. The second use of systematic is to refer to the range of phenomena covered. In this way, systematic refers to the comprehensiveness of the science. Thus physics, which is the systematic science par excellence, proceeds methodologically by subjecting highly developed theoretical postulates to the test of critical experiment. Its systematic hierarchy of theories comprehensively covers almost the whole range of physical phenomena. From the application of higher mathematics to physical theory we may deduce the actual physical behavior in a wide variety of fields which appear phenomenally quite different. For many years there has been no serious controversy concerning the general outline of physical method and with the application of this systematic method, the frontiers of our knowledge of physical phenomena have been gradually increased.

Until very recently, psychology has been a somewhat heterogeneous mass of schools or systems rather than being systematic. The individual system in psychology usually was the working out of one man's or some group of men's particular methodological bias and applying this to a more or less limited range of behavioral phenomena. These schools or systems varied in regard to what was the proper scientific method for psychological investigation, in their basic postulates, and in regard to the particular problems to which they were applicable. Thus there was no real agreement concerning either the method of psychology or the nature of its subject matter until fairly recently. Even twenty-five years ago, the difference between the adherents of Titchenarian structuralism and the emerging Gestalt psychology of Wertheimer was so great that the naive student would scarcely be able to recognize that they were concerned with the same science. Similarly, the original Watsonian behaviorism and Freudian psychoanalysis were also not only in great disagreement with each other, but with the other two schools already mentioned. It is quite natural that in the early days of any science such a variety of theories and methods and such varying opinions concerning subject matter should arise. Psychology, covering as it does the whole gamut of total behavioral reactions of the personality, is a very broad field and many of its problems may be stated in such

SYSTEMATIC PSYCHOLOGY.—There are two aspects of modern science which may be called systematic. The first of these is methodological and is concerned with the ways in which the empirical and theoretical aspects

a way that the outcome of their investigation depends on the original basic postulates of the investigator.

Today, however, the leading adherents of all of the schools have come to considerable agreement concerning both the method and the subject matter of psychology. In fact, the contemporary behaviorists have been forced to deal with problems of motivation and the unconscious and so have had to take cognizance of the factors which the psychoanalysts had previously looked on as their particular subject matter. Similarly, the Gestalt psychologists and the psychoanalysts have been forced to deal with their subject matters with that greater rigor of scientific methodology which was the chief positive contribution of the behavioristic revolt against traditional introspective psychology. Thus Lewin, a leading exponent of Gestalt psychology, writes that he believes psychology is now in a position to go beyond the schools through the development of basic agreement on what constitutes methodology. Hull, an equally outstanding theorist of modern behaviorism, attempts in his most recent writings to set up basic postulates of behavior, which will form the cornerstones of all of the behavioral sciences. And finally, there has been a growing tendency amongst psychoanalysts to subject their doctrines to critical examination in light of their scientific adequacy and thus make psychoanalysis simply a part and a method of general psychology. Despite this contemporary striving towards a systematic psychology, both with regard to its methodology and comprehensiveness, there still remain some differences regarding what constitutes a basic philosophy of biology for psychology, the nature of the scientific method as applied to psychology, and the nature of the language of science between the adherents of some of the traditional psychological systems. The following paragraphs will give both the general points of agreement and the points where further clarification is necessary with regard to the method and subject matter of psychology as these are viewed by the leading contemporary behaviorists, Gestalt psychologists and psychoanalysts. Particular reference will be made to the present positions of Professor Clark Hull as an exponent of modern behaviorism, Professor Kurt Lewin as an exponent of the most important methodological developments stemming from Gestalt psychol-

ogy, and the position of the orthodox Freudian psychoanalysts.

To a certain extent the method chosen for scientific investigation in any field must stem from philosophy. Philosophy, as the mother of all the sciences and the source of undifferentiated knowledge within the sciences, is bound to influence the individual investigator, be he conscious of this or not. Throughout the 19th and early 20th centuries, there was a great deal of debate concerning the general nature of biological phenomena, particularly the position of man in nature. Before systematic psychology as we know it today could develop, the philosophical antithesis between vitalism and mechanism had to be resolved. This antithesis—as is so often the case in the development of philosophical thought—could not be resolved through the choice of either of these, but rather through their synthesis into the new doctrine of organismic theory. Vitalism, which regarded man as a machine plus some sort of organizing principle such as the *élan vital*, the *entelechy*, or soul, was opposed by mechanism which regarded man simply as a machine. The vitalistic approach gained few serious adherents because it was early realized that the postulated organizing force was not subject to scientific verification and consequently represented a scientifically meaningless postulate. Atomistic mechanism supposed that biological phenomena must be reduced to physics, whereas vitalism believed that biology could not be reduced to physics. Both of these philosophies of biology, however, lead to an analysis which was primarily structural. The mechanistic position which seemed almost unavoidable so long as physics depended on mechanics rather than modern dynamics, ran into difficulties in attempting to account for the organization of the parts into the whole organism. Machines require engineers and, while vitalism met this problem with the postulated unobservable causal force, mechanism was simply unable to meet it. With the development of modern dynamic field-theories of physical behavior, it became possible to look on biological phenomena as organismic in nature, as organized systems of energy in which the organism in its organizational aspects represented a more or less subcontained system roughly analogous to certain physical closed systems or fields. This led to the possibility of stressing functional rather than structural analysis and

to the proposition that biological phenomena were not necessarily deductible from physics, but rather that both physics and biology followed the same sort of general logical dynamical propositions. Thus today, systematic psychology is more and more based on the organismic philosophy of biology which supposes that the organism represents a system of energy rather than a machine, where analysis of a functional or relational nature is indicated and where dynamic theory plays the same type of role which it does in physics. Certainly all serious attempts at modern systematic psychology are based on an explicit or implicit acceptance of the organismic philosophy of biology. This has important implications for both the method and the subject matter of biological science. Psychology investigates the total or integrated behavior of the psychological organism in all of its ramifications and it does so by using a dynamic methodology.

As until recently there was much debate between the adherents of various underlying philosophies of biology with regard to the method and subject matter, so there was also a considerable difference of opinion regarding the basic investigational method in psychology. Natural sciences were usually considered to be empirical and inductive as opposed to the philosophical sciences which were largely based on deductions. Psychology, as a growing natural science, tended more and more to depend on the experimental or other observational gathering of data without reference to specific theoretical constructs. Just as the mechanists were opposed to the vitalists regarding the philosophy of biology, so the inductivists were opposed to the deductivists concerning how, in practice, psychology should go about gathering its data. The inductivists believed that measurement and observation would lead to laws which were the expression of correlations between events and which could be summarized in theories if necessary. Conventional deduction was considered as the inversion of induction without the experimental procedures. This antithesis regarding method was again resolved by the synthesis of both positions into what has been called the hypothetical-deductive method, which supposes that the empirical and theoretical aspects of science are quite inseparable. According to this view, the growth of science occurs when a "hunch" gives rise to working hypotheses

which may be verified in experiment and which in turn will lead to new hypotheses of a more general nature. From the very first, theoretical constructions are utilized, not only to order and explain the empirical findings within the science, but to lead to the empirical substantiation of predictions, which may not be made on the basis of common sense experience, and so to broaden the breadth and the validity of the first postulates. Modern systematic psychology has become very sophisticated with regard to the use of theory. Thus the original behaviorists, who believed that they were creating a purely empirical objective science of behavior have given rise to the modern behavioristic psychology as exemplified by Hull, which purposely uses theoretical constructs of a very sophisticated sort in the nature of intervening concepts. The original Gestalt psychologists have been forced to introduce more and more mathematically defined explanatory constructs of a field-theoretical sort and psychoanalysis has greatly increased the number and complexity of its theoretical constructs. The theoretical as opposed to the empirical part of a systematic science consists of hypotheses of a generalized nature; laws, which are expressions of the application of theoretical constructs to limited systems; and the system itself, which refers to the largest generalization of empirical data. The explanatory process in natural science supposes that a natural event is to be explained from a theorem or set of postulates derived by the deductive process of reasoning. Natural science more and more resembles the type of logical hierarchy which is found in its purest form in geometry and in its most important applied form in theoretical physics. The hypothetical-deductive method is a method through which the descriptions of behavior in ordinary language are translated into the theoretical constructs of the system. Constructs are abstractions which give us schematic interpretations to account for the essential descriptions of experiments and behavioral observations may also be called descriptions in terms of genotypes. A genotype is a description in terms of the language of the theoretical constructs used in the hypothetical-deductive method. Thus, as psychology becomes systematized through the use of the hypothetical-deductive method, constructs play an ever larger role. This is true in modern behaviorism which makes increasing use of inter-

vening variables, such as habit strength, reaction potential, reactive inhibition, and oscillation; in Gestalt psychology, which makes increasing use of conceptions like vector, region differentiation in the personality, levels of reality and aspiration; and psychoanalysis with its conceptions of basic libidinal and destructive urges, the conscious and unconscious, and ego, superego, and id. With the introduction of theoretical explanatory constructs comes the tendency to attempt a greater precision in their definition and a greater logical stringency in their derivation and interrelationships. This leads to the attempt to mathematicize concepts because the applications of algebra and geometry to concepts makes it easy to get the universal consent of competent observers to these, which is the aim of all science. Thus at the present time, there is rather general agreement that systematic psychology must be hypothetical-deductive in its methodology and although various investigators still use constructs which are not completely inter-translatable, there is still a much greater possibility of agreement concerning the meaning of concepts than was previously possible.

With the general agreement on the organismic philosophy of biology and the importance of the hypothetical-deductive method, the type of theory accepted by systematic psychologists again becomes very similar in the leading schools. The approach to behavioral problems becomes more what has been called field-theoretical. The field concept in biological science is taken over as a general analogy to the field concept as used in physics in the gravitational and electro-magnetic fields. In any field, the behavior of an object is determined by the structure of the field rather than inherent forces within the object itself. A field represents an organized system of energy in which the distribution of forces within the field depends on the pattern or arrangement of the field rather than on the simple sum total of the parts. Forces within the field show the properties of vectors—that is directed magnitudes whose direction or amount is determined by the total distribution of energy. In field theories, events are never locally determined but are determined in terms of the functional interrelationship between the objects which make up the field. Field theories allow no dichotomies as between the abnormal and the normal, for instance. Thus modern systematic psychology tends to

become more field-theoretical and there is a general agreement that psychology is the science of the behavioral adaptation of the individual organism in its total surrounding environment.

Thus from the standpoint of method, modern psychology may be called systematic. It advances by subjecting constructed theories to the test of critical experiment. The adequacy of the constructed theory to account for a comprehensive variety of behavioral phenomena and the stringencies of the definition and the logical interrelatedness of the explanatory constructs both vary in the hands of different expositors. Of all of the contemporary positions that of modern behaviorism, as represented by Hull for instance, is most systematic in the care with which the intervening variables or constructs have been defined and related to each other. On the other hand, the behaviorists' system at present can deal only with very limited and somewhat artificial situations concerning the modification and the integration of very simple responses to very limited stimulating situations. The field-theoretical or topological approach of Lewin is based on concepts which are methodologically quite similar to those of Hull, but which are not as precisely and operationally defined. Concepts like the psychological field with its variations of person structures, reality level, and vector, barrier, and goal, cannot be subjected to the exact algebraic mathematical treatment which Hull is able to give habit strength, reaction potential, reactive inhibition and oscillation. They are, however, applicable to a much wider field of adaptive behavior in terms of human psychology than are those of Hull. The constructs of the psychoanalyst, such as libido, ego, id and superego, are logically and definitionally perhaps less adequate than either of the above. They are applicable, however, to the most complex of human adaptation problems through the whole range of both abnormal and normal mental phenomena. With regard to method, we may finally say that there is an encouraging general agreement concerning method amongst modern psychologists which allows us to assert that the systematic position of psychology has increased with increased rapidity in the last twenty-five years.

Modern psychology has also increased in its systematic aspect with regard to the comprehensiveness of the range of phenomena cov-

ered. If physical laws are gradually enlarged to account for physical happenings throughout the whole physical universe, psychological laws and theories likewise have become increasingly generalized. This has largely been due to the application of the hypothetical-deductive method and the introduction of genotypical explanatory concepts. Such genotypical concepts allow, as we have seen, no dichotomies. The original academic scientific psychology of Wundt and his followers was concerned chiefly with the structural aspects of the normal adult human mind. Modern systematic psychology goes beyond this to develop general principles which will apply to the abnormal as well as the normal, the child as well as the adult, and the animal as well as the human, and it has increased its interest from the simple structural or descriptive analysis of consciousness to an attempt at functional analysis of all behaviors, both conscious and unconscious.

This has come about through the application of the organismic philosophy of biology and the wider use and understanding of the hypothetical-deductive method. It has also been facilitated by an increasing interest in the problem of motivation which recently, after long being one of the peripheral or borderline problems of psychological research, has become essential to psychological research in its systematic aspects. Earlier theories of both the structural and behaviorists' schools were but little concerned with motivation. Practically all modern theories now accept it as a starting point. Thus the dynamic aspects of behavior tend to become stressed rather than the structural aspects of behavior. Although no theories of motivation at present will completely account for all behavior, there is an increasing agreement that motivational factors must be postulated and they become essential to modern behaviorism, modern Gestalt psychology and psychoanalysis. The interest in motivation itself has probably been the chief and necessitating reason for the invention of theoretical constructs. Thus the behaviorists are more and more concerned with drive and its experiential modification and are less and less able to attempt to account for behavior simply by accepting an irreducible minimum number of innate behavior patterns and attempting to add these together in a truly summative factor to account for complex behaviors. More and more behaviorists are con-

cerned with drive, its frustration and the resulting effects of frustration of the drive. The field-theoretical approach from the standpoint of Gestalt psychology has stressed internal psychological tension and the blocked goal situation from the very first. Motivational problems, thus, also play a large role in the modern field theories. Finally, of course, motivational problems are essential to systematic psychoanalysis.

With motivation as the central problem of systematic psychology, the other problems derive from it and enlarge upon it in a more systematic fashion. Thus all of the investigators in modern times have been interested in the problem of the effect of frustration of motivated behavior upon the individual in both its long time and short time aspects. Undoubtedly, of all the approaches here, psychoanalysis has been the most systematic in working out all of the ramifications of this problem. From the central concept of motivation, we develop interest in the problems of resultant personality structure and this leads into the field of individual differences which in turn leads into the whole field of applied psychology.

The relation of psychology to the other sciences depends on the basis on which psychology is systematized. Insofar as we today accept the hypothetical-deductive method, psychology takes its place amongst the systematized and general basis sciences. It becomes foundational to all of the social sciences on the one hand and it becomes the culmination point of all of the biological sciences on the other hand. Depending on whether the constructs are derived with reference more to physiological problems or to social problems, systematic psychology becomes more physiological or social in its basic principles respectively. Of the three chief types of systematic psychology herewith discussed, modern behaviorism in the nature of the problems studied and in its experimental methods is most closely related to physiology, whereas psychoanalysis with its emphasis on interpersonal relations is most closely related to the social sciences. Modern Gestalt psychology falls some place between the two. Since physiological methods of investigation allow a more stringent experimental control, the methodological advantages of modern behaviorism are quite obvious. The present tendency, however, is for modern behaviorism to attempt to give its exactitude and precision to problems which are

more social and hence more vital, whereas the tendency of psychoanalysis (particularly since the development of psycho-somatic medicine) has been towards the greater precision in its observational methods and the correlation of its theoretical constructs with physiological findings. Thus there is every evidence that within the next period of psychological development, the subject matter of psychology will become as systematized as we have now found its methods to be.

In summary, psychology as a science is growing beyond the schools and personal systems and is becoming systematized along the same line as physics and the older sciences. Systematic science uses a common method—the hypothetical-deductive method—and we have seen that there is general agreement on this in all modern positions in psychology. Systematized science further tends to be comprehensive with regard to the range of its subject matter. Contemporary psychology moves along these lines as the problem of motivation has become central. Although there continues to be a greater interest in some of the problems which range into the social amongst psychoanalysts and a greater interest in the problems which range into the physiological amongst behaviorists, the present at-

tempts of behaviorists to deal more and more with social problems and of psychoanalysts to deal more and more with physiological problems should bring about an increased agreement concerning this second systematic aspect of psychology. At the same time, modern Gestalt psychology with its field-theoretical approach has logical and experimental implications for physiological problems on the one hand and for social problems on the other seems destined to take an intermediating position between the other two approaches. Thus in final analysis, psychology is becoming systematic in both its methodology and comprehensiveness.

WAR AND PEACE.—Clausewitz, the famous military theorist, wrote that "War is nothing but a continuation of political intercourse with a mixture of other means." Actually, war and peace can only be understood in relation to each other, just as "heat" and "cold," instead of being antithetical phenomena, come to be understood as different manifestations of molecular motion. The basic patterns of human interaction are continuous; the specific form of violence called war is an expression of trends clearly observable during peace.

Further, war and peace co-exist simultaneously. At the time when men of one nation are warring against those of another, the relations of men within each nation are peaceful. When one class or political sect wars against another, the relationships within each group are usually peaceful and cooperative in character—perhaps even more so than in the absence of external war.

War is a manifestation of organized aggression. It is not, however, directly comparable to the expression of aggressive impulses in fighting between individuals. Individual fighting implies at least some awareness of the preceding circumstances and goals sought; for most of the combatants, war includes no such awareness. Nevertheless, the ultimate explanation of war must be based on the same aggressivity which is released in fighting.

Psychologists of the nineteenth century were attached to the concept of a "pugnacious instinct" and attributed wars to this dynamic force (McDougall, 4). Orthodox Freudians accept an analogous concept of a "death instinct" (Menninger, 5). These theories have sometimes been misinterpreted as implying that war is inevitable because of human nature. Neither conception is necessarily related to such a view. Aggression, even if instinctive, could be channeled into other paths than war. In 1932 Fletcher queried several hundred American psychologists, many of whom believed in one or the other of these theories, regarding the notion

that human nature made war inevitable. Well over 90 per cent rejected this idea.

Under conditions of peace, men inhibit overt expressions of hostility (under pressure of law and custom). Competition takes economic and political forms, both within the nation and between nations. When war is declared, the taboo on violence is lifted as regards citizens of the enemy nation; in fact, such violence is socially ordered and approved.

In attempting to analyze the change from a peace pattern to a war pattern, we must differentiate among individuals. The actions of a small group may be far more potent in restructuring the situation than the contrary actions of a much larger group. The decisions that shaped Japan's course toward domination of East Asia, or of Germany toward Lebensraum, were made by a small minority in each case. We must distinguish, therefore, between the psychology of leaders and of followers in the transition from peace to war.

Leaders are, by definition, persons who have privileged position in terms of wealth, power, or both. To expand such holdings may be the primary goal in their acts (Japanese monopolistic enterprises in Manchuria, Nazi preferential trade agreements in the Balkans and in South America). The decision to resort to force for the sake of gaining such economic goals, or for the sake of holding such possessions against seizure, or for the sake of achieving greater power, may thus be considered a relatively rational motivation, in so far as the welfare of the leader is concerned.

This quest for power and privilege takes place initially on a peaceful basis. Competitive business and diplomatic practices precede all armed conflicts. When these fail to reach a culmination reasonably satisfactory to all concerned, the resort to war becomes imminent.

Modern war requires the active support of the majority of the followers, and passive acceptance by all but a small minority. This state is achieved by virtue of a number of pre-condi-

tions which are present in almost all modern societies: (1) a substantial residue of repressed aggression within every individual, which can be directed into belligerent channels; (2) a distorted perception of the people who live in other nations or other social groups; (3) an identification with and feeling of loyalty to the social group and its leaders, and a need to feel secure in this relationship; and (4) a desire for vicarious satisfaction of such impulses as the power drive, through exaltation of the group with which the individual is identified.

War occurs because of the conditions of peace. A majority of American psychologists appear to reject the notion of an instinct of pugnacity, replacing it by the view that aggressive impulses are an outcome of frustration. A certain amount of frustration is inevitable in the process of becoming socialized; far more than this minimum of frustration is encountered by the average person. Poor living standards, a lack of prestige, insecurity are some of these frustrations. The average citizen thus has a great potential reservoir of hostility which cannot be openly vented because of the taboo on violence within the social group.

Such aggression often is not directed to its real cause: economic conditions, social organization, or direct physical deprivation. It may, instead, be displaced onto foreigners, Negroes, Jews, Communists or some other irrelevant scapegoat group. If leaders, through speeches, newspaper articles or other media, spread the view that "our group" is menaced by an out-group, this repressed aggressivity may be channeled into conscious belligerence directed against the menacing group as defined.

The importance of increased frustrations in making this possible can well be demonstrated by the development of the Nazi Party. Founded in 1920, the Party in 1928 was polling less than 5 per cent of the vote in German elections, and claimed about 100,000 members. By 1930 the membership had jumped to nearly 400,000 and by 1932 skyrocketed to about 1,000,000. The vote showed a similar sharp rise, to 40 per cent of the total cast.

During this interval there was no change in the character of the Party, as regards leadership or propaganda. The same "menaces" were dangled before the German people: Russia, Communism, England, France, Jews. The crucial difference between 1928 and 1932 was in

the economic welfare of the population. In the latter year depression and hardship had resulted in greatly increased suffering and frustration, with a consequent magnification of the amount of aggression ready to be displaced against these alleged enemies. The result was, if not a popular majority for Hitler's belligerent program, at least a very large block of support for it. Under conditions of severe economic deprivation, we can anticipate that similar leadership would be accepted by citizens of other nations.

The displacement process has been demonstrated in so many clinical, statistical and experimental studies that it is no longer a matter of controversy. Considerable doubt remains as to the elasticity of the process: the extent to which any group X may become an object of collective antagonism by the process sketched. The limits are probably set by perceptual patterns which have been determined by early experiences, education, etc. Considerable flexibility is indicated by the fact that Japan and Italy fought with the Allies against Germany in World War I; that England and France were "hereditary enemies" for centuries; that the Prussians were praised highly by British newspapers during and after the Napoleonic campaigns, etc.

The perceptual process itself is of course not independent of motivational determination. The maxim that "we see what we want to see" is still true. We can, however, identify independent environmental factors which facilitate this change from perceiving neighbors as friends and customers to perceiving them as enemies and barbarians.

Stereotypes. As the child matures, he acquires from his culture not only certain habits of behavior, but also certain pre-formed pictures. The American child assimilates stereotypes of Negroes, Jews, Frenchmen, Russians, etc., with predictable regularity. This mental picture, which is surprisingly impervious to the effects of actual personal experiences, determines the child's expectancies and interpretations with regard to the behavior of these outside groups. Thus, a lynching by Southern whites is interpreted as normal behavior toward a Negro, whereas less brutal behavior by Russians may seem more heinous, because of the stereotyped picture of Russians. Face-slapping by an American girl is amusing; by a Japanese, it is an "atrocious." (The learning function in-

volved in this process has been well analyzed by May, 3.)

Our acts and attitudes are determined by that which we believe to have happened, as much as by what actually happened. Peace will lead to war, therefore, so long as education, the newspapers and family conversation build up these intensely unfavorable stereotypes of all foreign groups. International peace is attainable only through cooperation between the people of different nations; but, as long as our pictures of others (and theirs of us) are so distorted, such cooperation is hardly conceivable.

Stereotypes of outgroups are heavily loaded with unpleasant characteristics by virtue of two processes, identifiable respectively as projection and animistic thinking.

Projection refers to our common tendency to see outside ourselves, elements which really are part of the Self. Thus, a strong sex urge may lead the person to believe that "everybody is over-sexed." "Cheaters" believe that others do a great deal of cheating. Very aggressive individuals see an excess of aggression on all sides.

Projection is most pronounced in relation to undesirable characteristics. The ego rejects the idea that it carries socially disapproved traits; instead, such traits are imputed to others. By doing so, a certain degree of release for the inhibited tendency is made possible. Self-appointed censors of burlesque shows, e.g., can see as many lewd shows as are available, without losing caste. The over-aggressive Hitler could point to "belligerent" France and Russia, thus justifying to his people the Nazi attacks on other nations. This type of propaganda was successful because it fitted in with pre-established stereotypes and was reinforced by the projection of aggressive intentions onto these other nations (Durbin and Bowlby, 1).

Animistic thinking generally identifies the common tendency to ascribe human psychological traits to the non-human environment. In the present context we are interested in man's tendency to ascribe his troubles to the malicious action of human agencies, rather than to impersonal natural or social forces. Primitive tribesmen blame crop failures on their neighbors; citizens of civilized nations ascribe economic depressions, lack of national prestige and other frustrations to the malice of neighboring states.

The term "black-white thinking" is some-

times used to refer to this composite of stereotyping, projection and animism. Each of us tends to think of his nation as pure and white; of foreign nations as evil and black. The intermingling of good and bad traits in every social group is overlooked. It is because of the prevalence of such thinking that an aggressive, war-breeding national policy is easily sold to the citizens.

Nationalism. The type of thinking just described is associated with a dynamic attitude known as nationalism. This is a convenient collective term for a set of inter-related beliefs and impulses: beliefs relating to the superiority of our nation and the inferiority of others; impulses aimed at the aggrandizement of our nation and the depreciation of others. Nationalism, of course, is but a specific case of the phenomenon designated as ethnocentrism. The members of a religious group or a labor union commonly manifest similar behavior regarding their organization.

The three characteristic elements of the nationalist attitude pattern are the delusion of national virtue, the delusion of national grandeur and the delusion of national persecution (cf. Stratton, 8). These are not equally present in all nationalisms; and it is only when the latter two are quite strong that we find a major menace to world peace.

The delusion of national virtue applies to the common beliefs in the purity of motives in national policy, the absence of aggressive wars in national history, and the high moral and cultural level of the population. Dynamically, it seems to involve a displacement of affection from the parents to national symbols. In all western culture the terms "fatherland" and "mother country" are common. The child tends usually to exaggerate the virtues and ignore the defects of his parents, and, later, of his nation. This view of the nation as parent-symbol is upheld by psychoanalytic observations of individuals (Hopkins, 2) and by statistical data on groups (Stagner, 6).

Delusions of national grandeur relate to the power of the nation, a quasi-divine mission to spread its domination over increasing areas, and a profound disregard of lesser peoples. These may be illustrated by the early American contempt for signed treaties with the Indians; British and Japanese imperialism; and in ultimate form, by the Nazi ideology. The dynamic

basis of this reaction pattern seems to lie in the displacement of desires for power and wealth from individual to national goals. The emotion of thrilled pride reported by most people watching demonstrations of national armed might supports this interpretation.

The delusion of national persecution centers around the belief—particularly characteristic of twentieth-century Germans—that other nations have conspired to prevent them from achieving their appropriate power and prestige, or that plots are now on foot to steal away such possessions. Such delusions are fairly general toward all foreign nations but pick out certain countries especially. Among European countries the fear of "Uncle Shylock" is pronounced; in the United States, suspicion of Britain and Russia is strong. Most of these reactions show the irrational characteristics of displaced aggression.

In common with the delusions of the neurotic and the psychotic, nationalism shows the characteristic reactions of repression and rationalization. Historic events which show the favored nation in an unpleasant light are conveniently forgotten. Other material is distorted, and some legends are complete fabrications. The stature of national heroes is enhanced, and the character of the population glorified by such devices. The irrational nature of this behavior serves to underscore the role of the emotional determinants of thought. Whenever deep loyalty to one group, or intense hostility to another, becomes a factor in one's judgments, logic loses ground in favor of wishful thinking. This is true, of course, regarding labor unions, church organizations and political parties, as well as nations.

Not all nationalism is war breeding. Pride in culture and affection for a locale are compatible with tolerance for others. When these characteristics are combined, however, with displaced aggressions and power drives, the result is likely to be disastrous. Obviously the same conclusion would follow from any other ethnocentric grouping: religious, economic or political, about which delusions of grandeur and persecution became organized.

Militarism. A third element facilitates the alignment of western populations behind leaders setting forth on an aggressive foreign policy. This is the glorification of war and fighting as good in themselves. We are quick to recognize this trait abroad but to ignore it at home. Our

history texts glorify the military commander; war-time presidents receive special fame. A pugnacious, reckless leader is praised for his courage; the cautious compromiser who keeps the peace is scolded for weakness.

While in peace-time there are few spokesmen who openly glorify war, there are many who exalt the deeds of past warriors and denounce any critics of war as an institution. The public schools teach the righteousness of past wars. Thus children acquire an attitude which, if not militaristic, is suitable for militarism to sprout, under appropriate conditions.

Scales for the measurement of "attitude toward war" administered in peace-time characteristically reveal the average man as neutral to mildly pacifistic rather than militaristic. Such observations are not of great significance, because the crucial peace-time policies which guide nations toward war are political and economic rather than military in character. It is none the less interesting that those groups which are most intensely nationalistic in their political and economic beliefs also exceed the average score for approval of war. Such groups include the organized veterans, persons of low educational status, etc. College graduates and members of pacifist societies are found to be strongly anti-war on these attitude scales, relatively low on nationalism.

The three factors sketched—stereotypes, nationalism, and militarism—show characteristic changes as a transition from peace toward war progresses. As media of communication carry predominantly unfavorable news about nation X, our stereotypes of X citizens take on a darker shade. Attention focuses on the necessity of action by our national government to protect its citizens; this intensifies nationalism. The feeling of persecution by X is likely to be strengthened first; then we intensify our delusions of virtue and grandeur. Militaristic attitudes seem to be last in developing, reaching the foreground of consciousness only when the conflict has gone too far for peaceful settlement. These generalizations, based on extensive data collected just prior to American participation in World War II, fit well with the interpretation of war already outlined. It would seem to follow that fundamental work on peace education must focus on breaking down stereotypes and building balances to nationalism, more than on militarism as such.

When compared with the period of tension leading up to hostilities, overt warfare shows only an intensification of trends already outlined. Dynamically the outstanding characteristic of the war period is the uncovering and release of tremendous aggressive impulses. For the soldier these may have self-preservative value, in that they motivate vigorous activity. For the civilian they are more of a problem. Even in a war plant it is difficult for him to feel that he is attacking the enemy directly. He does not have adequate outlets for his aggressions. The result is, only too often, attacks on radical groups, industrial leaders, racial minorities, etc. The inevitable frustrations of war-time living generate aggression which, for the soldier, is generally canalized into fighting; for the civilian, it may set off violations of necessary governmental regulations.

During the war the perceptual distortions associated with stereotyping, projection and animism are also intensified. The enemy becomes a complete concentration of evil. For this period, stereotypes of our allies may acquire a favorable tinge. This friendly reaction among Americans to Britain and France disappeared rather rapidly after World War I. The patterns established by many years of peace-time competition take precedence over the cooperative attitudes generated during a short war.

For the participants, warfare has many unpleasant aspects; yet it also has numerous gratifications. Our attention is naturally directed first to the release of aggression; some individuals get intense pleasure from uninhibited killing. Hopkins tells of a patient, a machine-gunner, who remained concealed until a column of Germans came quite close. He then opened fire, wiping out most of the enemy. He related this incident with obvious glee.

Beyond this elemental pleasure in destruction, soldiers also have extensive opportunities for exhibitionism, upon which many seize joyously. Most men have been frustrated in their desire to be the center of attention; as soldiers, this desire is gratified. Sexual mores are relaxed; the man in uniform has unprecedented opportunities for sexual gratification. Barracks life and continued close association with men seem to satisfy a repressed homosexual tendency in many cases. The break from dull routine, possibly from an unsatisfactory home life, and

opportunity for exciting adventure, also constitute compensations in a large number of cases. It should be emphasized, however, that such considerations have nothing to do with the occurrence of war; they are incidental by-products.

As has already been intimated, the goals which are decisive for the transformation of peace into war are those of a relatively small leadership group within a nation. In a very large number of cases, the goals involved are economic: seizure of an area rich in natural resources, protection of a preferred trade position or the destruction of competitors. In other cases the goal is primarily political: the capture or retention of power. Thus ruling groups resort to war as a "lightning rod" for revolutionary tensions within the nation; both the Romanoffs and the Hapsburgs are reliably reported to have been influenced by this consideration in 1914. The mechanism relied upon is displacement of hostility from the ruler to the foreign foe. (The device is successful only occasionally, although it has been recommended to monarchs since the time of Aristotle.) By judicious appeals to nationalism, the method succeeds temporarily; but if the war leads to hardships, revolutionary tendencies may reappear in more violent form.

The analysis so far is closely compatible with the views of experts in economics and political science (cf. Wright, 9) in so far as the impact of the social environment on the individual causes war. That it is possible to reduce the tensions of peace, and thus to decrease the probability of war, is a logical conclusion from these facts.

A number of prominent social psychologists were polled in 1942 (Stagner, 7) on long-range and short-range methods of rendering peace more stable. The short-range program endorsed was composed of familiar elements: a League of Nations, an end to imperialism and economic nationalism, giving the League veto power over national laws likely to set off international conflict, etc. It was conceded by most of the group that such a program was not probable of adoption, since it would run counter to irrational but powerful nationalist prejudices.

As a long-range program, therefore, the group favored ideas focusing around two themes: (1) that a decrease in the general level of frustra-

tion will weaken the aggressive tensions which might, through displacement, become a dynamic impulse toward war; and (2) that education for insight into such aggressive tensions would make displacement and irrational hostility less frequent and less dangerous.

Lowering the aggressive tension level calls for a decrease in biological and ego frustrations. Industrial democracy, a guaranteed minimum standard of living, consumer cooperatives, are some of the specific devices approved. These would raise the level of biological security and also free the average citizen from many ego deprivations which today are characteristic of our culture.

The so-called "sublimation" approach to world peace, identified with William James' famous essay, "The Moral Equivalent of War," was not endorsed by this group of psychologists. Believing as he did in instinctive pugnacity, James naturally advocated a program calculated to drain off in less harmful ways the aggressivity now canalized into war. Items introduced into the questionnaire to exemplify this approach were approved only by a minority of those answering. Forestalling aggression by avoiding needless frustrations appeared a more hopeful course.

It is recognized, none the less, that some minimum of frustration is inevitable. The child cannot be socialized without frustration of desires, and social living will inevitably entail some compromising of impulses. To channel the resulting aggression into constructive or harmless paths is the task of education.

Giving more people more education—even of the sort prevalent today—would help in the development of tolerance, reduce scapegoating and increase somewhat the chances for peace. To do its job competently, however, education should be basically reformed. The ideal educational program for war prevention would be constructed on a mental hygiene model, with less emphasis on traditional subject matter, more on human relationships (cf. Mark May, 3). Self-insight would be a primary objective. The control and direction of aggressive tensions into relatively constructive channels would be an important goal. Teachers would aim at breaking down black-white thinking and at preventing the growth of stereotypes.

Self-insight is integrally related to the preservation of world peace because it is only with

insight that reason achieves control of individual behavior. A man who lacks understanding of his own emotions and motives easily falls prey to propaganda based on economic, religious or racial prejudices; he may be induced to project aggression onto foreign peoples, and to anticipate attack in a wholly unrealistic fashion; he readily represses material conflicting with tendencies of positive emotional value, and he therefore acts in an irrational manner. The aggressive foreign policies which lead to war are popular with those whose thinking follows this pattern. An intelligently critical attitude toward war-breeding activities of national leaders is impossible except as the individual can assess and allow for his own emotional biases.

Except as an incidental by-product of some extracurricular activities, the control and direction of aggressivity have never been considered legitimate goals of education. Although the schools have required much memorizing of facts, they have done little with the problems of anger and hostility. Such teaching as we occasionally find is on an unrealistic level, urging the use of "will power" to control such tendencies. As anyone who has worked with aggressive children can testify, much more than will power is needed for success. The techniques which have been found satisfactory in the clinic (dismembering dolls, destroying valueless objects, expression followed by analysis) can and must be applied in the ordinary educative situation. As children become capable of understanding and dealing with their own inner impulses toward aggression, they will become more tolerant and less susceptible to blind prejudices against religious, racial or national groups.

This process will be aided by teaching aimed at preventing the formation of stereotypes. In this respect some schools have already made progress. Recognition of positive contributions by all ethnic groups is necessary. The prevalence of good and bad characters on both sides of boundary lines must be stressed. The recurrent tendency to polarize (categorize all incidents at one extreme or another of a continuum) must be persistently combated.

In striving for a general recognition of the essentially human character of all groups, we must develop in children the ability to identify themselves with others. This is necessary if the

Germans (for example) are to pause in the act of planning an aggressive policy toward Poland and ask themselves, "How will the Poles feel about this?" Mutual identification is necessary if representatives of two groups are to reach a harmonious settlement of conflicting tendencies. A general capacity for identification would render less probable any endorsement of imperialism and exploitation.

Education must have as its primary aim—above the three R's, above vocational training, above the classics—the development of an emotionally mature population. The policies which cause war between nations, churches, races and classes are policies which appeal to the emotionally childish.

The irrational quest for power through group action oppressing other peoples is a symptom of emotional immaturity. A belligerent insistence upon "our rights," without consideration of the rights of others, is equally immature. True cooperation between nations calls for an end to the type of animistic thinking which blames all our troubles on foreign enemies. It demands the acceptance and tolerance of differences between peoples, instead of attempting to force our standards upon all others.

It will not be enough to have realistic, emotionally mature leaders. They are always subject to replacement by neurotic demagogues if the general population is emotionally susceptible to the thrill of promised national grandeur, the phobia of national persecution and the sadism of group intolerance.

Economic and political reforms are important. Our economic system sets a pattern of selfishness which inevitably establishes a non-cooperative frame of reference. The fiction of absolute sovereignty must be replaced by an awareness of limited sovereignty in an inter-

dependent world. The cooperation displayed within a nation at war must be extended across boundary lines. Peace must be so structured that the average man can live a life of comfort, self-respect and hope for the future of his children. Political institutions must be set up to pattern for man's thinking the model of peaceful cooperation instead of war as the norm of international relations.

In this, as in so many other respects, it is difficult and even dangerous for a single nation to act in isolation. We shall need cooperation between groups in the various Great Powers, striving toward these goals more or less in parallel. A major problem in applied psychology, this task has so great significance that it merits unlimited effort. There seems no other pathway to an enduring peace.
